both Lewis and Krogh place dermatographism in line with exaggerated normal reactions of the skin to injury. According to their view a mechanical stimulus produces more histamine in an urticarial subject than in an ordinary subject, and that the urticarial subject reacts more strongly by virtue of the greater amount of histamine set free. This setting free of greater amount of histamine is due to greater susceptibility of the cell elements to injury in the shape of unusual fragility, etc. We have already mentioned that our case exhibited a stronger reaction to histamine than normal individuals so that we cannot accept that the whole of the difference in susceptibility to injury of urticarial patients is due to the difference in the amount of production of histamine and not to any difference in susceptibility to histamine.

(2) Walzer (1928) takes objection to the position taken up by Lewis and Krogh, and states that dermatographism is a pathological condition and not an exaggerated normal one. He is inclined to the view that the presence of dermatographism indicates some general internal pathologic process. He stroked the skin of the backs of 48 persons, cases of mild skin diseases, and as controls, of thirteen subjects with urticaria and pruritis. Out of the 48 only 11 responded with a weal after from eight to twelve consecutive strokes over the same area; all the weals were mild, some extremely so, and could be felt rather than seen. Out of 13 patients with urticaria and pruritis 11 responded with a weal on a single stroke only. The poorest reaction in this group was much more pronounced than the best reaction in the previous group.

He next tried if urticaria factitia could be experimentally produced by injecting the serum of a dermatographic patient into the skin of a normal person, and then stroking these sites of injection. He used sera of 10 dermatographic cases and each serum was injected into at least 5 or 6 different persons. A dermatographic state was produced on the skins of non-dermatographic subjects with the serum of only one of the dermatographic patients. From this he concludes that although the presence of a transferable dermatographism-inducing principle in the blood stream of an average patient with symptoms of urticaria factitia cannot be demonstrated with this technique, its existence cannot be excluded as it is possible that in the blood of the average patient it may be in too high a dilution to manifest itself by this procedure.

Walzer contests the assertion of Lewis that all weals are fundamentally the result of a common causative factor—'a liberated substance or substances having a histamine-like action'. Injection of the serum of a patient in whom a dermatographism-inducing principle could be demonstrated did not produce any weal at the time of injection, but it induced a state of altered reactivity so that trauma at a subsequent date produced a dermatographic response.

Had this dermographism-inducing principle been like Lewis' H substance the injection of the serum into normal skin should have induced a histamine weal at once.

Description of the case.—An Indian male, aged 20, suffering from dermographia for the last two years. No history of urticaria or other skin allergy in the family.

Blood count.—Total leucocytes 20,000 per c.mm.

Total eosinophiles 1,000 (5 per cent) per c.mm.

Large mononuclear 400 (2 per cent) per c.mm.

Lymphocyte 3 per cent.

Polymorphonuclears 63 per cent.

Blood calcium 0.0098 per cent, or 9.8 mgms. per 100 c.cm.

Histamine dermal test.—Positive with 1/2,000,000 dilution—negative with 1/20,000,000 dilution.

Intra-dermal test.—Positive with 1/20,000,000 dilution, lower dilution not tested.

Desensitizing with histamine.—Desensitization was started with 0.1 cubic centimetre of 1/20,000,000 dilution. The dosage was gradually increased and a maximum dose of 0.3 cubic centimetre of 1/2,000 dilution was reached on the fourth day. On the fifth day the dermal and intra-dermal tests with histamine were repeated with the following results:

Dermal test.—Negative with 1/20,000 dilution, higher dilution not tried. (On the first day the test was positive with 1/2,000,000 dilution.)

Intra-dermal test.—Positive with 1/2,000,000 dilution, negative with 1/20,000,000 dilution. (On the first day positive with 1/20,000,000,000 dilution.)

Discussion

(1) Lewis and Krogh believe that hyper-sensitiveness of the skin of an urticarial case is really a susceptibility of its cell elements to mechanical injuries whereby a greater amount of histamine is produced than normally. There is a good deal of evidence that urticaria factitia can be produced by local changes in the tissue cells alone. Walzer and Walzer (1928) showed that stroking some of the sites of previous experimental weals reproduced weals at these sites a few days later. Similar trauma, applied to any other part of the surface of the skin at the same time, resulted only in the usual erythematous response, demonstrating the fact that the reaction was purely a local one. Fulleborn (Walzer, 1928) found that weals resulted from the penetration of stronglyloid larvæ into the skin. Stroking these particular areas within 2 or 3 weeks after the weals had gone, he elicited weals at these sites. Bettmann

(Walzer, 1928) demonstrated urticaria factitia over tattooed areas in a series of about forty-one patients. The subjects were not dermographic and had never had any urticaria. Rubbing or stroking the tattooed areas reproduced the outlines of the tattooed figures in weals.

(2) Lewis does not give any place to the increased reaction to histamine in the causation of urticaria factitia, as he finds that dermographic subjects are only sensitive to histamine to the same extent as a normal person. Krogh, although believing that the variations in susceptibility of individuals to different forms of tissue injury are largely to be explained as variations in histamine production, does not forget that they may be to a minor but unknown extent due to variations in reactions to histamine. The reaction to histamine in the case of dermographia described by us clearly shows that increased reaction to histamine plays some part at least in bringing about dermographism.

(3) That a dermographism-inducing principle circulates in the blood of at least some cases of dermographism is quite evident from Walzer's case in which he produced a dermographic state on skins of non-dermographic subjects by injecting the serum of a dermographic patient. Moreover we have seen dermographism in cases of filarial infection. We believe that in dermographism we have to deal with all these factors—(i) abnormal state of the tissue cells, this may be inherited or acquired as in Walzer's, Fulleborn's and Bettmann's cases, (ii) increased reaction to histamine, and (iii) the presence of some general internal pathological process. We have no evidence to show, but it is very probable, that this third factor works in association with decrease in pituitary hormone which Krogh has shown is responsible for maintaining the tone of the capillaries. It is quite conceivable that on account of deficiency of this hormone the permeability of the capillaries is increased, and that the toxin, whatever it is, can penetrate the capillaries more easily and that its action on the tissue cells is more apparent, making them hyper-sensitive to injury and the H substance.

Calcutta*

and

GURBAKSH SINGH CHOPRA, M.B.B.S. (Punj.)

Research Assistant

*(Drug Addiction Inquiry, Indian Research Fund
Association)*

Series No. 17

In a previous paper (1928) the senior author stated that addiction to purified alkaloids of opium was a rare occurrence in India. In western countries morphine and of late years codeine and heroin also have been extensively used. In view of the fact that habitual use of alkaloids, such as cocaine, is being gradually introduced into India from these countries and from the Far East, the Drug Addiction Inquiry has been keenly on the lookout for extension of the morphine habit or habitual use of any of the other alkaloids of opium in this country. During the course of our field work in Northern India recently we have seen quite a number of cases of addiction to morphine, though not to codeine and heroin. Further enquiry into the matter elicited the fact that habitual use of morphine had undoubtedly increased in certain parts of India during the last few years. The increase at present is very small and only a few areas here and there are affected, but there appears to be a grave danger of its extension, if steps are not taken to meet the evil.

Source of supply.—Instances of the abuse of morphine were undoubtedly met with in the past, but these were uncommon. Further the drug was almost always taken by the mouth, but lately we have seen many instances where the alkaloid is being taken by injection; this increases the danger of the habit for reasons discussed later. In spite of the vigilance of the excise authorities there appears to be no difficulty in procuring the drug for euphoric purposes. We have been informed by the addicts themselves that the alkaloid can be bought in any of the large towns in Northern India without difficulty. The following are some of the avenues by which the drug finds its way to those addicted to its use:

(1) The use of morphine appears to have been encouraged and the alkaloid obtained through the agency of 'medical practitioners' who are holding licenses to stock and dispense this drug. The law in this country as regards registration of medical practitioners is not strictly enforced and there are numbers of unqualified persons practising in almost every town and village, who are not borne on the medical register of the different provinces. Some of these individuals have managed to get licenses to keep morphine for sale and they have been abusing the privilege. A careful

examination of the daily sales-register of one such licensee showed that morphine in the guise of prescriptions was being regularly sold to a number of people throughout the year. Out of 200 legal sales by this person during the year 1931-32, there were none below 1 grain, i.e., about 4 times the usual therapeutic dose. The following is a sample of the prescriptions written by one 'practitioner':—

Liq. ammon. acetat	..	4 drachms.
Spt. ammon. aromat.	..	4 "
Sod. bicarb.	..	3 "
Pot. iodide	..	1½ "
Syrup tolu	..	1½ "
Morphine sulph.	..	12 grs.
Aqua chloroform.	..	12 oz.

Dose—1/12th part to be taken 3 or 4 times a day, or

Morphine sulphate 24 grs.

Divide into 12 powders.

The alkaloid was shown to be prescribed in the treatment of asthma, abdominal troubles (diarrhoea and colic), insomnia, joint pains, etc., but it was really being given to persons who had formed the habit and were addicted to the drug. Some of these licensees are addicted to morphine themselves and play a part in developing the habit in others and disseminating the use of the drug by telling people of the wonderful effects produced by it in various conditions.

(2) Besides obtaining the drug by false prescriptions there is another source from which the supply of morphine comes into the hands of addicts. We have been informed that there is some leakage from large hospitals and medical institutions, and a certain amount of the drug is stolen and sold to dealers who pass it on to the addicts.

(3) The drug has also been obtained through apparently legitimate sources. In one of the towns we found that a number of addicts were taking large doses of morphine daily and were getting the drug from the license holders in the ordinary way. Their names were borne on the register of the excise authorities and they were issued with regular permits to buy their daily rations.

Careful inquiries in various places showed that the drug was not being smuggled from foreign countries as is the case with cocaine. This is due to the fact that at present there is a small demand for it and it is not worth the while of the smugglers to be interested. If, however, the habit spreads more the smuggler will become interested and will try to push the contraband trade.

Morphine habit among Indians

(1) *Euphoric use.*—It has been possible for us to study quite a number of persons addicted to morphine. The causes which lead to this addiction among Indians do not differ from those producing other drug habits. The habitual use of morphine in this country resembles

the cocaine habit as described by Chopra (1931). The habit is very seldom started for its sedative and analgesic properties as it is in western countries, but indulgence is practically always started on account of the sense of euphoria that it is said to produce. Persons, taking narcotic drugs habitually, often extol their virtues and relate the wonderful effects produced by them to their credulous friends. The types of individual most attracted by such descriptions are young persons between the ages of 20 and 35 who are induced to try the drug entirely for production of euphoria. Sexual factors also play a very important part so far as this class is concerned. The majority of these addicts believe that morphine has remarkable power as an aphrodisiac, and in quite a large number of cases they started using the drug for this reason. The alkaloid is at first used occasionally and the fact is kept secret. Repeated use of the drug however quickly leads to habit formation and these young adults become slaves to the habit. The stage is soon reached when morphine is the only drug which relieves them of their imaginary mental and physical troubles.

Psychopaths and neurotic individuals are particularly prone to contract the habit and one dose of the drug leads to a great craving for another, and the dose is rapidly increased. Most of the morphine addicts we have met in India have belonged to these two groups. Although the large majority of those seen by us were males, we have been credibly informed that the habit is not uncommonly met with among the females of certain classes in large towns.

(2) *For the relief of pain.*—Although the morphine habit in western countries, in a very large majority of cases, is started after its use for relief of bodily pain, this appears to play very little part so far as the Indian addicts are concerned. In fact in the series of cases we have studied there was not a single individual whose habit could be directly assigned to the use of the drug for bodily pain, either on the advice of a medical man or by way of self medication. Our experience is that opium and morphine are prescribed to a much smaller extent by the Indian practitioners than by their confrères in the west. The use of the drug for relief of pain, fatigue, insomnia, etc., has only rarely given rise to the habit. Such addicts are as a rule persons of middle age and very often they are aware of the harm the habitual use of the drug is doing them and therefore increase the dose very gradually.

(3) *As a substitute for opium or to cure opium habit.*—We have met a number of instances where people taking large doses of opium have resorted to the use of morphine, hoping that this will enable them to cut down the quantity of their opium consumption. Some have gone so far as to hope that this would rid them of the opium habit. The result often

is that not only do the addicts not succeed in getting rid of the opium-eating habit, but they begin to take morphine in addition to the usual quantity of opium. Persons interested in the sale of morphine often urge that it is cheaper to replace opium with morphine and that there is less likelihood of forming a habit with it, but this is a deliberate falsehood. Such statements have however been responsible for producing the morphine habit in quite a number of ignorant persons.

Modes of administration.—Morphine is taken by the Indian addicts in two ways :

(1) *By the mouth.*—This was the method which was used almost exclusively till a few years ago. The reason was that it was often used as a substitute for opium and the addicts preferred to take it in exactly the same way as they did opium. When the drug is taken in this way the effect of the dose is prolonged, but it is not so lasting as opium because its absorption from the gut and its excretion are much quicker.

(2) *By injection.*—The difficulty of performing the operation of injection, which requires some skill, has stood in the way of this method being used to any great extent in the past. It has however come into vogue recently and during the course of our work in the field we have encountered instances of this method of administration of the drug amongst the laity. Septic infection and even death from tetanus have resulted among addicts. The advantage of this method, from the addicts' point of view, is that the effects are almost immediately obtained and are more intense, but the disadvantage is that duration is much shorter. In consequence there is greater desire for the repetition of the dose and the abstinence symptoms are much more intense.

Dosage.—The average dose of the alkaloid taken by the addicts in our series is between 4 to 6 grains daily. The common practice is to take it in the morning and evening whether by injection or by mouth. There is a great tendency towards increasing the dose among the addicts who take it to produce euphoria and in neurotic individuals. We have found persons taking as much as 10 to 20 grains a day. A case was reported from the North-West Frontier Province in which as much as 60 grains a day were taken by injection.

Age and duration.—In the majority of cases studied the habit was said to have been contracted between 18 and 35 years of age. Addiction to opium, on the other hand, is more commonly seen in persons after the age of 40, it being essentially a habit of middle age. In the areas where a large number of addicts were seen, in the majority the habit had not lasted for more than 4 or 5 years. Practically all the addicts who practised injection had been doing it for less than six years. A few addicts who took morphine by the mouth said they had

done so for 10 to 15 years, but such long duration was uncommon. Evidence at our disposal points to the fact that the pernicious type of addiction is to be met with only amongst the youths in this country, it is of recent origin and has only developed during the last 5 or 6 years at the most.

Symptoms and effects.—Chopra and his collaborators have fully discussed in a series of papers (1927—1932) the effects produced by the opium habit among Indians. During our study of the present series of morphine addicts we tried to observe if there were any marked differences in the symptoms and effects produced by the two drugs, opium and morphine. So far as the immediate effects of taking morphine by the mouth are concerned, these do not differ materially from those produced by opium except that the onset perhaps is more rapid. A dose of opium taken by the mouth usually takes 10 to 15 minutes before its effects are manifested whereas morphine taken by the mouth takes 5 to 10 minutes. The effects of injection are however manifested within a few minutes and the feelings of elation and euphoria are much more pronounced after an injection.

In their later effects opium and morphine whether taken by the mouth or by injection differ a great deal and we will refer to these differences briefly. The physical examinations carried out in a number of cases showed that most of the habitués were well-built, but they all looked pale and anæmic. The pulse and respiration were rather slow, the blood pressure was below normal and the pupils were generally contracted. The tongue was thickly coated and the bowels were constipated. As already stated morphine is habitually used in India almost entirely for its euphoric effects and for sexual gratification by young and middle-aged persons. Opium as a general rule is taken habitually by the older people and generally for disease and old age. The morphine habitué shows the physical effects much more rapidly than the opium addict. Within a year or so the former becomes pale and emaciated, and begins to suffer from symptoms of cachexia. Opium addicts, even those taking moderately large doses, go on for many years before they show any apparent signs of degeneration. Morphine addicts soon become physical wrecks while opium addicts take a long time to reach this stage. The blood pressure is perceptibly lowered in morphine addicts while in opium addicts no such effect is produced.

When under the influence of morphine the addict looks worried, depressed and hypersensitive, whereas after a dose of opium he is cheerful, care-free and talkative. Persons taking small doses of opium carry on their work quite well, but those taking even small doses of morphine are unable to concentrate and show a general lack of responsibility. There is impairment of memory, and judgment is

disturbed. Mental and moral deterioration sets in more rapidly and is much more marked in morphine addicts, who will often commit criminal offences. In opium addicts mental deterioration occurs much more gradually and only when large doses are taken. Abstinence symptoms are much stronger among morphine habitués than in those addicted to opium and there is also a greater tendency for the dose to be increased. The morphine habit is much more difficult to break than even the opium habit.

Summary and conclusions.—Habitual use of morphine has increased in India during the last few years. The increase at present is small and only a few areas here and there in Northern India have been affected. There appears, however, to be grave danger of its extension, if steps are not taken to check it.

The habit in India is usually met with in young persons between the ages of 20 and 35 years. The habitual use of morphine in this country resembles the cocaine habit to a great extent. The habit is not started for its sedative and analgesic effects as in western countries, but for its euphoric effect and because of its supposed aphrodisiac properties. Formerly the alkaloid was taken almost exclusively by the mouth but recently the injection method has come into use.

Various factors in connection with the types of addicts, the dose taken, duration of the habit, comparative effects produced by opium and morphine habits among Indians have been discussed.

SOME FACTORS REGULATING METASTASIS IN CARCINOMA AND THEIR INFLUENCE ON PROGNOSIS

By M. N. DE, M.B., M.R.C.P. (Lond.)

Professor of Pathology

and

S. C. SINHA, M.B., B.Sc.

Demonstrator of Anatomy, Medical College, Calcutta

It is a general rule that when a malignant epithelial neoplasm grows in any part of the body the tumour cells tend to burrow their way into the lymphatic spaces and spread along these channels. Hence extension and dissemination of the growth take place along the lymph channels. Sooner or later, however, some of the atypical cells reach the general circulation through the thoracic duct. In the circulation they may either be dissolved by the cytolytic action of the blood or they may reach the lungs through the pulmonary artery and act as emboli, which may be the starting points of metastatic nodules.

Before the cells can reach the general circulation, they must pass through lymph nodes, which are thus involved one after another. In the lymphatic glands the tumour cells get ample nourishment, and consequently multiply very rapidly and produce masses of growth which ultimately replace the parenchyma of the glands and cause various grades of glandular enlargement. Towards the beginning, these glands act as efficient filters preventing the onward passage of the neoplastic cells, but when the gland tissue is considerably replaced, this protective power goes and the cells then begin to pass into the next group of glands, *via* the intervening lymph channels.

It is thus evident from the above well-established facts that, for the dissemination of a carcinoma, the integrity and potency of all the lymph channels are essential factors. If therefore these channels are obliterated, as sometimes they are, by a chronic sclerosing type of lymphangitis, it becomes difficult for the cells to pass into and reach the proximal lymph nodes. The carcinoma will, in that case, have no other alternative but to grow locally, and extend by local tissue destruction. The inception of this factor in the course of the neoplasms will have a significant bearing on the duration of the disease which may be prolonged for

many years. The following interesting case may be cited as an illustration:

Case report.—An adult, Hindu male, aged 35 years, a carpenter by occupation, noticed a swelling the size of a marble on the left scapular region in 1923. It continued to grow, rather slowly at first, till it burst, forming an ulcer, which failed to respond to ordinary treatment. Two years passed, the ulcer increased in size, and the patient sought for relief in the hospital.

Condition on examination (*i.e.*, in 1925): The ulcer area was 3 by 5 inches in size, and presented a very foul-smelling ulcerated area covered with patches of slough. The entire mass was firmly fixed. The character of the surface, base, and edges suggested a typical cauliflower-like carcinoma. A piece of tissue removed from the edge proved, on histological examination, to be epidermoid carcinoma. A thorough clinical search failed to reveal any glandular involvement. Considering the lymphatic drainage of the parts one would have expected the subscapular group of the axillary set of lymphatic glands to be enlarged, but such was not actually the case.

Fig. 1.

Operation.—A complete excision of the ulcer with all suspicious tissues and scraping of the scapular group of muscles were undertaken. A very large bare area was produced which took a long time to heal, ultimately requiring skin-grafting. The patient was under observation for nearly three months, but made a complete recovery.

After-history.—The patient had no trouble till 1930, *i.e.*, after the lapse of 5 years, when he noticed a swelling in the same region. This also burst and an indolent ulcer was produced. He came again under observation in 1933. The condition on admission may be realized from the photograph (figure 1). The growth measured

(Continued from previous page)

Chopra, R. N., Grewal, K. S., Chowhan, J. S., and Chopra, G. S. (1930). Addition to 'Post' (Unlanced Capsules of *Papaver somniferum*) in India. *Indian Journ. Med. Res.*, Vol. XVII, p. 985.

Chopra, R. N., and Knowles, R. (1930). The Action of Opium and Narcotine in Malaria. *Indian Journ. Med. Res.*, Vol. XVIII, p. 5.

Chopra, R. N., Mukherjee, B., and Dikshit, B. B. (1930). Narcotine: Its Pharmacological Action and Therapeutic Uses. *Indian Journ. Med. Res.*, Vol. XVIII, p. 35.

8 inches by 6 inches. The edges were everted and indurated, and the base fixed to the underlying tissues. A very careful search on this occasion again failed to reveal any enlargement of the lymphatic glands. Nor was there any clinical evidence of metastases anywhere else in the body, except a swelling on the adjacent part of the posterior aspect of the middle of the arm which was evidently due to local extension. The lungs were normal but no skiagram could be taken as the patient suddenly left our hospital. Although the scapula was movable, there was some limitation of movement of the shoulder joint obviously due to adhesions and loss of muscle tissue.

Discussion.—It seems probable that the growth originated in a sebaceous gland, either as a primary condition or as a secondary superimposed condition brought about by irritation of an ulcer by the application of the irritating country medicines. Whatever might be the

Fig. 2.

origin, there was no doubt that it was a malignant growth and as such should have involved the proximal lymph nodes by metastasis. But, on both the occasions when the growth was examined, the lymph glands were found to be conspicuously free. The malignancy of the epidermoid group of carcinoma may not be very great, when compared with the carcinoma of the breast or alimentary tracts, but early glandular involvement of the part affected is the usual feature.

This would suggest that either the cancer cells could not reach the glands through the lymphatic channels which were rendered too narrow for the passage of the comparatively big squamous cells, due to some sort of obliterating lymphangitis, or that the cells, although they reached the glands, could not grow and multiply owing to the early development of

cytolytic factors. Ulceration in an exposed part in an illiterate patient with little sense of cleanliness might have induced sufficient inflammatory reaction to cause occlusion of the lymph channels in the surrounding areas. Moreover it is definitely known that the growth of a carcinoma and the infiltration of carcinoma cells in the tissues sometimes excite a very marked proliferative tissue reaction in the neighbouring areas; such chronic inflammation may often produce a barrier to the further extension of the growth by the deposition of fibrous tissues, as is very well known to occur in the case of scirrhus carcinoma of the breast of long duration. Another effect of such long-continued inflammation may be the formation of many foreign-body giant cells, which are set up against the invading carcinoma cells causing their ultimate destruction (*see figure 2*). The result of the action of all these has been that the growth has remained strictly local, and its malignancy consequently has also been a local one. The outcome of such alteration is not without its value to the patient, for it not only gives a longer lease of life to him by preventing a generalized dissemination, but also presents a very suitable local condition for complete cure by modern surgical methods, such as excision by diathermy alone, or combined with the application of accessory therapeutic agencies, such as x-rays and radium.

But when we consider that even after a complete excision with sufficient healthy areas to ensure a thorough removal there was a recurrence, it becomes rather difficult to understand why the growth should be mild enough to leave the lymph nodes of the parts untouched.

It will be seen that the total duration of the carcinoma from the time of its first appearance to the time the man came under observation for the second time was ten years, and that during all this time it remained only locally malignant. We looked into the references at our disposal, but could not find any record of an epidermoid carcinoma remaining only locally malignant in spite of its power of recurrence during such a prolonged period as ten years.

Summary

Metastasis in carcinoma usually takes place through the lymphatics, but, in the late stages, it may be through the general circulation. Involvement of the proximal lymph nodes within a reasonable period is the rule.

Occlusion of lymph channels by inflammatory changes prevents the extension of malignant epithelial growth into the lymph glands and prevents their enlargement.

For the same reason such growths remain locally malignant and can only extend centrifugally by local destruction of tissues.

MIXED TUMOUR OF THE FACE, NOT ASSOCIATED WITH THE PAROTID GLAND

By P. N. RAY, B.A., M.B. (Cal.), F.R.C.S. (Eng.)

Hon. Surgeon, Carmichael Medical College Hospitals and Additional Surgeon, General Hospital, Howrah

A MIXED tumour of the face unconnected with the parotid salivary gland is of sufficient rarity to warrant the detailed study of a single case. Additional interest is attached to the following case because the greater part of the tumour was composed of a large single translucent cyst. In this brief review, an attempt has been made to summarize the essential features of the few cases that it has been possible to collect from the literature.

The present case

S. B. G., Bengali female, aged 18, married. (First examined by me on 2nd October, 1932.)

History.—A small rounded painless nodule about the size of a pea was noticed three years ago, over the left side of the face. Originally of slow growth, the tumour rapidly increased in size to that of a walnut, during the last five or six months.

No other member of the family was affected.

On examination.—The tumour was situated over the left side of the face about half an inch in front of the lobule of the ear and about an inch above the lower border of the body of the mandible. The overlying skin was telangiectatic and adherent to the tumour for an area half an inch across. No punctum could be discovered. The tumour was smooth, rounded, fluctuant and translucent. It was freely movable over the deep fascia.

Corresponding cervical lymphatic glands were not enlarged. No other tumour was present on the body.

Operation was postponed on account of seabies from which the patient was then suffering, and she had a subsequent attack of influenza.

Two months later.—The tumour increased to a diameter of nearly 2 inches. On operation, a clear fluid of a pale yellow colour was withdrawn. On microscopic examination, neither epithelial cells nor cholesterol crystals were found.

Operation.—The tumour was excised under local anaesthesia with all the adherent skin, and a free margin of healthy tissue. It was surrounded on its deeper aspect by a sort of fibrous capsule. There was neither any adhesion to the deep fascia nor any connection whatever with the parotid gland.

Macroscopic appearances.—The tumour, submitted for examination, was covered with intact epidermis. It was placed in a hardening solution, containing formalin, whereby the fluid contents of the large cyst were converted into a homogeneous transparent jelly. On section, the inner lining of the cyst was smooth, but

intracystic projections were present on the floor. The cyst, forming the greater part of the tumour, was situated beneath the superficial solid part, which was only about half an inch in thickness and presented a semi-translucent surface, mottled with whitish areas of denser growth.

Microscopic appearances.—The histological picture is a complex one.

(i) The continuity of the epidermis with the cells of the neoplasm cannot be traced anywhere, but telangiectasis is marked (figure 1).

Fig. 1.—Photomicrograph (low power). (1) Epidermis with telangiectasis. (2) Large cyst. (3) Solid part of the tumour.

(ii) The epithelial cells are arranged in columns, masses and in places in alveolar formation enclosing a homogeneous material, but the reproduction of the dermal glands is nowhere clearly attempted. In some places, the cells are small and compact with scanty protoplasm and hyperchromatic nuclei, resembling those of the basal-cell carcinoma (figure 2).

Fig. 2.—Photomicrograph (magnified). (1) Small cysts lined by basal cells. (2) Palisade arrangement of the outer layer of cells. (3) Connective tissue matrix showing hyaline change and cylinder formation.

There are also solid anastomosing strands or cords, with club-shaped prolongations of which

(Continued from previous page)

Such a pathological condition, of necessity, will very much prolong the duration of the disease and lengthen the life of the patient. It also provides the surgeons with a suitable opportunity for totally eradicating the disease.

A case has been described in detail, in support of the above observations; in this case the total duration of the disease was over ten years.

the outer cells are columnar and are arranged radially in palisade formation. Prickle cells are absent and so are keratinized 'cell-nests'. But numerous cystic areas are included among the larger cell masses. Some of the smaller cysts are lined by the basal cells (figure 2). Mitosis is infrequent.

In some places, the cells tend to become flattened and spindle-shaped and to form compact masses in which hyaline intercellular substance appears in increasing amounts. This appearance resembles that of the endothelioma (figure 3).

Fig. 3—Photomicrograph, showing the main tumour mass.

(iii) The supporting frame-work of connective tissue also presents a varied appearance. Between the epithelial masses, there is a fibro-vascular stroma, which resembles the corium with its capillaries. In places, it has undergone a hyaline change, but there are areas where a definite cystic change has occurred or

Fig. 4.—Photomicrograph (high power). (1) Intracystic papilliferous projections on the floor. (2) Cystic contents. (3) Roof formed by a compact mass of cells.

where cylinder formation is marked (figures 2 and 4).

(iv) The large cyst has a thin floor, formed by a few layers of well-staining cells of the squamous type. The roof, however, is formed by a compact mass of epithelial cells, which are continuous with the body of the neoplasm. In places, intracystic papilliferous projections are present, but these are not well marked. The cystic contents are homogeneous in nature, and are stained pink with van Gieson stain (figure 4).

Commentary

There has always been much dispute regarding the origin of the mixed tumours of the parotid region. According to McFarland (1927), only very few cystic tumours of this region have been described. He is of opinion that nearly all, if not indeed all, of the so-called adenomas are but mixed tumours of unusual appearance. In 1911, Vincent described a tumour of 24 years' duration as a cystic adenoma of the parotid, which, though of slow growth, rapidly increased in size during the last four years to a diameter of 10 centimetres. It was cystic and when punctured permitted the escape of sero-sanguinous fluid. Brunschwig (1931) has recently described a subcutaneous mixed tumour of the face, not associated with the salivary glands. Patey (1931) observes that the mixed salivary tumours are a composite group of epithelial tumours, the varying pathological features of which depend on the degree of differentiation attained and the rapidity of the division of the cells.

Discussing the theories of origin of these tumours in Choyce's (1932) *A System of Surgery*, Back states that the primitive and varied nature of the component cells is readily explained by the embryonic theory of origin. This view receives wide support at the present time, especially from the French writers. The tumours are supposed to be derived from islands of embryonic cells, sequestered during the development of the mouth and face, and included in or near the salivary glands, most commonly the parotid. This process has been called by them 'enclavement', and the new growth the 'enclavoma'. Regarding the encapsulated or extra-glandular type of new growths, Benedict and Meigs (1930) state, on the authority of Ewing, that these may take the form of a basal cell or adenoid cystic epithelioma. These probably arise from misplaced and occasionally embryonal portions of the gland tissue. Bronchial remnants may be connected with this group. These are, by many authorities, classed with the teratoid tumours. They consider that mixed tumours are essentially benign but recur locally with great frequency. These rarely become malignant.

McFarland (1926) has made the strong statement that nothing of prognostic value results from the microscopic study of a mixed tumour. These contain varying quantities of cellular tissue of different kinds. Among them are the so-called 'indifferent cells', which in their most primitive form resemble the short spindles of sarcoma. When the opinion that these cells were derived from the endothelium prevailed, they were thought to be a step to the sarcomata; but with the discovery that they are in all probability embryonal, epidermal and epithelial cells, their presence becomes of no significance with regard to the sarcomatous nature of the tumour in which they occur. Professor Kettle (1928) says that a highly malignant tumour, viz, the teratoblastoma, may occur in the parotid region. It is however a great rarity. The main mass of the tumour is composed of small rounded or oval cells of a distinctly sarcomatous type, lying in a loose oedematous or connective tissue matrix. Fry (1927) supports the view that these tumours are entirely epithelial in origin. Some of the tumours show varying degrees of malignancy. There is no definite dividing line between the innocent and malignant and some of the more malignant may show many of the features typical of the innocent type of tumours.

In this connection mention has to be made of the cylindroma, which is now regarded as a variety of endothelioma. Histologically, the cylindrical hyaline structures are seen to be formed by modification of the connective tissue stroma or of the walls of the blood vessels, although in some cases such hyaline masses appear to be found in the middle of the tumour cells. This has given rise to much confusion, as their structure is often seen in the basal-cell carcinomata. In a recent report of a case of cylindroma with multiple tumours of 17 years' duration, Nicolas, Massia and Lebeuf (1932) state that clinically the new growths appear to them to be benign but the histological picture is analogous to the basal-cell epithelioma. Borst (1922), however, has described a tumour of the skin, as an endothelioma derived from the lymphatic endothelium. The cells are smooth and flattened, and they form a net-work of solid strands and cords embedded in a connective tissue matrix. These cells show their primitive character in that they do not usually form the typical endothelial tubes as in the lymphangioma. Kaufmann (1929) is inclined to support the view of Krompecher that these are basal-cell tumours. A group of tumours of the skin, presenting the structure of cylindroma, was long regarded as endothelioma (Ewing, 1931). A typical case of this class and one much referred to is that of Braun. This tumour was shown by Krompecher to be of epithelial origin and is now generally grouped with the epithelioma adenoides cysticum of Brooke. It occurs in the form of nodular painless tumours of the skin, especially of the head and neck. These appear about the age of puberty and do not exceed the size of a pea or a bean. These tumours are derived from the basal cells of the epidermis and the hair follicles.

Ewing (1931), however, says that a single bulky tumour of similar structure may occur in the skin and the subcutaneous tissue about the face and the neck. Krompecher (1922), who introduced the term basal-cell carcinoma, speaks of the basalioma, or the cystic sebaceous adenoma, containing colloid cell cysts, which are comparable to those of the adamantinoma. According to him, this tumour also occurs on the face and is similar to the baso-cellular epithelioma and it may show, in parts, a cylindromatous or cystic structure.

Conclusion

The mixed tumour, described above, presents many interesting features. Basal cells are present and some of the smaller cysts are also lined by basal cells. It is known that the mixed tumour may take the form of a basal-cell tumour or the adenoid cystic epithelioma. But where the cell masses are more compact, the cells tend to assume a somewhat irregular form. Histologically the tumour has to be differentiated from the endothelioma. Every unusual tumour that lacks easily recognizable characters stands an excellent chance of being labelled an endothelioma. Further, the atypical endothelioma can scarcely be regarded as having an established position. It is true that in this case there is a tendency to cylinder formation, but it is a peculiarity which is seen in other tumours besides the cylindroma. The diagnosis of an atypical endothelioma is admittedly difficult. Professor Kettle (1928) has laid down the excellent dictum that the negative properties of a cell cannot demonstrate its origin, and it is only when the cells of a neoplasm present positive evidence of their endothelial nature that we are justified in calling the tumour an endothelioma.

With regard to the formation of the cystic spaces, two interpretations are possible, either these are due to degeneration of the stroma or these are the result of desquamation or the secretory activity of the cells of the neoplasm (Kaufmann, 1929). It is exceptional to find such a large cyst containing clear fluid.

There is no doubt that the varied natures of the component cells and the supporting stroma are readily explained, if the tumour is regarded as an 'enclavoma' of embryonic origin. The new growth (described above) is therefore diagnosed as a mixed tumour of the parotid region, of the extra-glandular variety.

Summary

1. A 'mixed tumour' of the parotid region, not associated with the parotid salivary gland, has been described.
2. The great bulk of the tumour is due to the presence of a single large translucent cyst, containing a clear fluid of a yellow colour.
3. Histologically, the varied nature of the component cells, the tendency to cyst and cylinder formation, and the infrequency of mitosis are noteworthy features.
4. The new growth has been diagnosed as an 'enclavoma' or a developmental tumour. It is possible that it has been derived from islands of embryonic cells, sequestered during the development of the face.

In conclusion, I wish to express my thanks to Dr. C. C. Bose, Professor of Pathology of the Carmichael Medical College, for his valuable help and suggestions, to Dr. D. N. Banerjee, for his help with the histological specimens and also to him and to Dr. P. C. Rakshit, for the photomicrography.

PANTOCAINE IN EYE-SURGERY*

By G. JOSEPH GNANADICKAM

Swedish Mission Hospital, Tirupatur, Ramnad District

Cocaine has so far held the field as the only satisfactory drug for surface anaesthesia in eye-surgery, but its toxic effect has always limited its use, and it is not often that the mydriasis and the slight paresis in accommodation that it produces are welcomed. Besides, the difficulty experienced in keeping an account of its use in conformity with the excise regulations has always made the eye surgeon long for a safer substitute. For these reasons, every surface anaesthetic that was put on the market was given an eager trial in this hospital, and we have now found pantocaine, which we have used on over 3,000 cases, to be an effective substitute for cocaine, with none of the disadvantages of the latter. Not being so toxic as cocaine, it also easily replaces novocaine for infiltration anaesthesia.

Para-butyl - amino-benzoyl - dimethyl-amino-ethanol hydrochloride, to give the full chemical name of pantocaine, is a whitish, odourless, crystalline powder, soluble in water. The solution stands any amount of boiling without decomposing and can therefore be sterilized easily, and it also keeps indefinitely without decomposition. In the presence of an alkali, however, the pantocaine base is precipitated in the solution. Its toxicity is just as low as that of novocaine, and is one-seventh that of cocaine. It is not a licensable drug.

Like cocaine, it paralyses the sensory nerve endings producing an anaesthesia of the superficial tissues of the eye, but it has no stimulant action on the sympathetic and hence the mydriasis and the contraction of the blood vessels seen in the use of cocaine are absent in

not injure in any way the tissues with which it comes in contact, including the corneal epithelium as well, provided of course the cornea is guarded from exposure and consequent drying.

There is a slight smarting when the first drop of the pantocaine solution is instilled into the conjunctival sac. It passes off in four or five seconds. The anaesthesia starts in fifty to eighty seconds, the time varying in different individuals. The effect of a drop lasts from eight to twelve minutes, but, when two drops or more are instilled with an interval of a few minutes between each instillation, the anaesthesia is prolonged and is more pronounced.

With a two per cent solution of pantocaine the anaesthesia comes on earlier, and is deeper and more lasting than with a one per cent solution. The one and two per cent solutions of pantocaine are as effective as the two per cent and four per cent solutions, respectively, of cocaine with regard to the depth of the anaesthesia, but with the former the anaesthesia starts earlier and lasts as long as with the latter.

The relative anaesthetic effect of cocaine and pantocaine was tried on 50 normal eyes. The comparison was made as far as possible on the same individual.

With a single drop of	THE ANAESTHESIA	
	Starts in about	Lasts about
Cocaine 2 per cent ..	100—120 sec.	6—8 min
Cocaine 4 per cent ..	90—120 "	7—12 "
Pantocaine 1 per cent	60—80 "	8—12 "
Pantocaine 2 per cent	50—70 "	10—12 "

The relative effect of the two drugs (pantocaine 2 per cent, cocaine 4 per cent) on the

	JUST AFTER INSTILLATION			3 HOURS AFTER INSTILLATION			AGE OF PATIENT
	Tension Schiötz	Reaction of pupil	Width of pupil	Tension Schiötz	Reaction of pupil	Width of pupil	Years
Right eye pantocaine 2 per cent.	20 mm.	Good	2½ mm.	20 mm.	Good	2½ mm.	20
Left eye cocaine 4 per cent.	20 "	"	2½ "	22 "	Sluggish	3½ "	
Right eye pantocaine 2 per cent.	22 "	"	3 "	22 "	Good	3 "	60
Left eye cocaine 4 per cent.	22 "	"	2½ "	28 "	Sluggish	5 "	
Right eye pantocaine 2 per cent.	35 "	Sluggish	3½ "	35 "	"	3½ "	35
Left eye cocaine 4 per cent.	35 "	"	3½ "	48 "	nil	6½ "	

pantocaine anaesthesia. Pantocaine has no effect whatever on intraocular tension; it does

pupil and intraocular tension on two normal-eyed people and in one glaucomatous case is shown above.

*Being a paper read before the Missionary Medical Conference held at Kodaikanal in May 1933.

The one per cent solution is used for all surface operations, such as removal of foreign

bodies on the conjunctiva or cornea, cauterization of corneal ulcers, and pterygium operations, and for the examination of photophobic eyes, and the two per cent solution for all intra-bulbar operations, such as cataract extraction, dissection and trephining.

As pantocaine has no effect whatever on the iris dilator or accommodative mechanism or intraocular pressure, it is an ideal drug for tonometry. One drop of the one per cent solution is enough for the purpose. The tonometer can be applied just a minute after the instillation.

In the fact that it has no deleterious effect on the corneal epithelium, pantocaine should have the preference over cocaine for all operative treatment of ulcers of the cornea.

For those who use a local anæsthetic for applying an irritant drug on delicate people, a half per cent solution is recommended. A drop or two of the two per cent solution injected under the muscles concerned, besides the drops on the conjunctiva, can be relied upon to give perfect insensibility for the muscle operations, such as recession and advancement.

As was mentioned above, pantocaine does not constrict the blood-vessel walls like cocaine; on the contrary, the smarting from the first drop of the solution causes a slight hyperæmia of the conjunctiva. So, for all operations, except perhaps the minor ones on the cornea, it is absolutely necessary to add adrenalin to the pantocaine solution to keep the operative field bloodless. We add two drops of the 1 in 1,000 adrenalin to each cubic centimetre of the pantocaine solution in whatever strength the latter may be used. The addition of adrenalin, besides inducing a local anæmia, augments the anæsthesia, making it more pronounced and more prolonged. It is possible that in some cases this pantocaine-adrenalin solution does not produce sufficient ischæmia, especially for cataract operations, and in such instances it may be necessary to instil a drop or two of the adrenalin 1 in 1,000 solution separately over the operative field.

For infiltration anæsthesia, pantocaine is used in 1 in 1,000 and 1 in 500 strengths; respectively, these are as good as, if not better than, the one and two per cent solutions of novocaine. Here also, the addition of adrenalin by two drops to each cubic centimetre of the fluid is essential for ischæmia and for increasing the intensity and duration of the anæsthesia.

Pantocaine can claim an advantage over novocaine in that the anæsthesia comes on earlier and is more lasting, and that the tenderness left behind in the parts infiltrated after the anæsthesia fades away is less. Incidentally, it is cheaper to use pantocaine in 1 in 500 strength than novocaine in two per cent or even one per cent strength.

Infiltration anæsthesia with	Starts in about	Lasts for about	Highest effect lasts for over
Novocaine 2 per cent with one drop of adrenalin to each c.c.m.	4-5 min.	2-3 hours	One hour
Pantocaine 1 in 1,000 with adrenalin as above.	5-9 "	1½ "	Half an hour
Pantocaine 1 in 500 with adrenalin as above.	3-5 "	5 "	Two hours

For orbital akinesia, for all operations of the lids and on the lachrymal apparatus, and for the retrobulbar ciliary block (which we use as a routine measure for most of the major intra-bulbar operations and for enucleation), we have found the 1 in 500 solution of pantocaine to give a uniform and perfect result, without in any way causing damage or irritation to the tissues infiltrated or producing any toxic effect.

We prefer to use the 1 in 500 strength to the 1 in 1,000 strength solution for the reason that the anæsthesia comes on earlier and lasts longer, though there is no difference in the depth of the anæsthesia in these two strengths.

Realizing the disadvantages attached to the use of cocaine for local anæsthesia, the medical profession has always wished for a substitute which is equally effective, but which at the same time is universally usable, relatively non-toxic and absolutely non-irritant in effect. While fulfilling these basic conditions for an ideal local anæsthetic, pantocaine can claim also to be comparatively cheaper, to be more stable in solution and to be more readily sterilized. To the eye surgeon, it further offers the advantage of not affecting in any way the pupillary width, the mechanism of accommodation, or intraocular tension, while keeping up the intensity and duration of the anæsthesia. Furthermore, pantocaine does not come under the purview of the Dangerous Drugs Act.

THE FREQUENCY OF HYDATID DISEASE IN INDIA

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
(From the Hookworm Research Laboratory, School of Tropical Medicine, Calcutta)

In the past, references have been made by many writers to the comparative rarity of hydatid disease in human beings in India, although it is fairly common in sheep and is sometimes found in goats.

The reason usually advanced for the relative freedom of human beings from this disease is that the dog, the host of the adult tapeworm (*Echinococcus granulosus*), is not such a close companion of man in India as it is in countries where hydatid disease is prevalent. This fact no doubt plays an important part in limiting

the transmission of hydatids to man, but there are other factors which are also of probably considerable importance. The first of these is that in India animal food is not nearly so plentiful as in other countries such as Australia, a notorious focus of human hydatid infection, and so the viscera (liver and lungs) are more carefully preserved for human consumption here and are not casually thrown to the dogs, as they frequently are in Australia. The result is that Indian dogs do not have the same opportunities of acquiring the infection from sheep. Climate is probably also of some importance because hydatid disease is mainly one of temperate regions. This is well illustrated in Australia where it is much commoner in the cooler south than it is in the tropical and sub-tropical north of the continent, notwithstanding the fact that conditions of life and opportunities of acquiring the infection are approximately the same all over the pastoral areas. On the other hand it is doubtful if the few cases that find their way to the larger hospitals give a true indication of the frequency of this disease in India, and whether there are not many unrecognized cases in the country districts.

Regarding the infection rate in dogs in India no literature is available as far as I am aware, and the only figures I have are those obtained from the examination of one hundred pariah dogs of Calcutta that were killed and examined for parasites in my laboratory at the Calcutta School of Tropical Medicine two years ago. Only two of these dogs harboured the worm *E. granulosus*. Dew (1928) stated that in Melbourne, Australia, dogs employed by butchers, drovers and farmers at the municipal abattoirs were infected to the extent of almost one hundred per cent. These dogs of course represent a highly selected class, and he goes on to say that dogs in other parts of the city show a very low infection rate and he quotes Clunies Ross in Sydney who found no dogs infected out of one hundred strays that he examined. Apart from the exceptional group of dogs in Melbourne referred to above, infection is much commoner in the country than in the city. In the grazing districts it is widespread and Dew quotes Clunies Ross who found that in New South Wales the infection rate in dogs in these areas varied between fifteen and sixty per cent with a general average of eighteen per cent. Therefore considering these facts and figures together with the small chance that dogs in the city of Calcutta would have of acquiring the infection, but where two in one hundred have been found infected, it seems very probable that *E. granulosus* infection is fairly common in dogs in the country districts of India.

Direct means of ascertaining the true prevalence of infection, either in human beings or in dogs, are not at present available in India, but a recent paper by Mahadevan and Menon (1933) presents an opportunity of obtaining

some indirect evidence regarding human infections.

The commonest site of hydatid infection is the liver, and this is clearly shown in the following table copied from Dew (1928). The second column indicates the figures for India.

Table of distribution of primary cysts (after D  v  )

		Percentage in Indian cases
Liver	.. 76.6	50
Lung	.. 9.4	5
Muscles and cellular tissues	.. 5.2	5
Kidney	.. 2.3	5
Spleen	.. 2.1	5
Bones	.. 0.9	0
Orbit	.. 0.7	0
Brain	.. 0.6	0
Miscellaneous	.. 2.2	30

Dew draws attention to the fact that seventy-six per cent for the liver is too high for cases in which the liver alone is involved, because in liver cases it is common to find other organs infected as well. And he says another error in figures of this nature is that owing to natural cure figures from hospital statistics probably place the infection rate in some organs too low. But as these factors will apply in any series of hydatid infections it seems that this table might be used for purposes of comparison with other records.

According to Mahadevan and Menon (1933) eight cases of hydatid disease have been recorded in the pathology department of the Madras Medical College. In this series four cysts were in the liver, two in the abdomen, one in the neck and one not known. The authors give particulars of seven cases of their own; three of these were in the liver, two in the peritoneal cavity, one in the kidney and one in the mammary gland. During the past five years four cases of hydatid have been seen in the Medical College, Calcutta; in two of these the liver only was infected, in one the liver, spleen and pelvis, and in the fourth the lung was the site of the cyst.

If the infection in which the liver, spleen and pelvis are counted as three we have twenty cysts to consider, and the liver is involved in ten, the abdomen (peritoneum) in five, cellular tissue (neck) in one, and the kidney, breast, spleen and lung in one each. These figures converted into percentages have been placed in a column beside D  v  's figures in the table. The five cases of abdominal hydatid have not been included in the table for Dew has excluded this type from D  v  's table also, because he says it is a common thing for cysts to be extruded unruptured from the liver into the peritoneal cavity where they acquire a fresh adventitious coat and may become attached to any of the organs covered by peritoneum, and it is therefore not possible to say whether they are

(Continued at foot of opposite page)

FURTHER NOTES ON PELLAGRA IN HYDERABAD DECCAN

By JOHN LOWE, M.B., CH.B.

Leprosy Department, School of Tropical Medicine,
Calcutta

Late Medical Officer, Leprosy Hospital, Dichpali,
Hyderabad

IN the *Indian Medical Gazette* of September 1931 the writer published an account of a series of cases of pellagra seen in the Leprosy Hospital, Dichpali, Hyderabad Deccan. The clinical manifestations were described as follows:— (a) dermatitis nearly always symmetrical, occurring most commonly on the back of the hands and the radial border of the forearms, and less commonly on other sites; (b) glossitis with excessive salivation; (c) nervous and mental symptoms sometimes culminating in suicide; and (d) gastro-intestinal symptoms (usually terminal). The mild cases showed only dermatitis and recovered; the moderately severe cases showed dermatitis and glossitis; and the severe cases showed nervous, mental and gastro-intestinal symptoms. The mortality rate was about 25 per cent. The causation of the disease was discussed but no definite opinion regarding causation was expressed. Of the cases reported in 1931 two more relapsed and died after the publication of the article. The other cases all cleared up but some had another attack a year later.

In the cold weather of 1931-32 a careful watch was kept for fresh manifestations of pellagra and 30 cases were seen. The first cases appeared in December 1931 and showed the typical dermatitis and glossitis, and the remaining cases were seen in January and February. We had a unique opportunity of watching the first signs of pellagra appear in

(Continued from previous page)

of primary origin. Dévé does not give a separate heading for the mammary gland so this case has not been included in the table either, but Dew states that the frequency of hydatid of the breast is 0.5 per cent.

At the first glance there appears to be a fairly close agreement between Dévé's figures and those from the Indian records, but Dévé's figures are calculated from 2,727 cysts and the Indian figures only represent twenty, so they are not comparable, and the fact that in such a small series as twenty cysts one each has been found in such comparatively uncommon sites as the breast, kidney, spleen and cellular tissue suggests the strong probability that the incidence of hydatid disease is commoner in India than the records in medical literature indicate.

lepers, and we have also observed pellagra in non-leper patients. Until 1932 we never saw a case outside this institution, though we had three patients with the disease on admission. Our observations in 1932 have shown that the disease is not confined to this institution, nor is it confined to those suffering from leprosy. We have now seen one case in a leper convict in Hyderabad Central Jail, three cases in lepers in villages, and two cases in villagers otherwise healthy. We strongly suspect that the disease is not uncommon in the general population of Hyderabad. Our observations of the onset of the symptoms of pellagra have led us to the following conclusions.

Hyderabad has a dry cool season with marked differences between the day and night temperatures, and between sun and shade temperatures. This produces in many apparently-normal people a peculiar condition of the skin, particularly of the hands, arms, feet, and legs, in which perspiration is slight or absent and the skin dry, and there is a tendency to ichthyosis. The most exposed parts of the limbs are affected most. There is a marked tendency to keratosis and cracks in the soles of the feet, less commonly in the palms of the hands. The lips are often affected, and soreness and cracks are common. This appearance of the skin is apparently due to exposure to cold dry air and to the sun. It is seen in a high percentage of village people in the cold season and of course these signs are not those of pellagra, but it is particularly in the patient in whom this condition is marked that definite symptoms of pellagra are apt to develop. This tendency to dryness and cracks of the skin of the limbs and lips, if marked, perhaps indicates a tendency to pellagra.

In people suffering from nerve leprosy, there is an additional cause of this tendency in the fact that leprosy itself frequently causes anhydrosis, dryness and cracks of the skin of the limbs, and once again it is such patients who are prone to develop signs of pellagra.

Early signs.—The first definite signs of pellagra observed were in every case either definite patches of dermatitis on the hands and arms or else glossitis. In our first report of this disease we described dermatitis as always the first sign to appear. More careful observation has shown that this is not so, and that glossitis is sometimes seen first and may precede the dermatitis by several weeks.

The complaint of glossitis is typical. The people of Hyderabad are very fond of curries highly seasoned with chillies, and when glossitis develops the soreness of the tongue prevents them from eating such highly seasoned curries because of the marked burning sensation produced. Sometimes when this complaint is first made, there is very little visible change in the tongue, but after a short time the change becomes visible. The tongue is at first rather swollen and red. The dorsum of the tongue is

usually lightly coated and the margins of the tongue show a characteristic appearance with

Fig. 1.—Pellagra—glossitis. Note swelling, enlarged papillae, and cracks of tongue; also blackening and desquamation of skin of lips and corners of mouth; excessive salivation (note saliva dropping from chin).

enlarged red papillae projecting above the surface. As glossitis progresses, in some cases cracks develop on the surface of the tongue which may present an appearance like syphilitic leucoplakia. With severe prolonged glossitis the tongue becomes denuded of epithelium and is small, atrophic and raw. The severer forms of glossitis are usually associated with inflammation and soreness of the lips, and of the mucous membrane of the mouth, pharynx and nasal passages. A typical case of severe glossitis with inflammation, cracks and blackening of the lips and the skin round the mouth, and with excessive salivation is seen in figure 1. The condition was associated with dermatitis and mental changes and later the patient died.

The distribution of the dermatitis we described carefully in our previous article. During 1932 we have been able to observe the early stages with greater accuracy. In most cases it starts as a small slightly-thickened erythematous patch on the skin on the dorsum of the hand between the bases of the thumb and the first finger. The erythema is transient, passing off in two or three days and leaving the epidermis thick, dry and a little blackened. This dark epidermis then cracks and desquamates in the centre, but the dermatitis tends to spread steadily over the dorsum of the hand (see figure 2) and up the radial border and back of the forearm. Unless the patient is seen

Fig. 2.—Hands of same patient as figure 1. Note symmetrical dermatitis with blackening and desquamation. This distribution of dermatitis is very typical.

in the first few days, the dermatitis on the hand may have nearly cleared up, and the forearms only may show dermatitis. The dermatitis rarely spreads above the elbow. Dermatitis usually appears first on the hand and arm, and in many of the slighter cases this may be the only sign present. Other cases show dermatitis on the dorsum of the feet and in other areas but here the patches are usually less defined. The association of dermatitis with exposure has been beautifully illustrated in some of our patients who wear sandals with a broad leather strap across the dorsum of the foot. In these patients the area covered by the strap was unaffected, the skin above and below showing dermatitis.

Recurrence.—Of seven patients who suffered from pellagra during the cold weather of 1930-31, and who recovered and were still under observation, two only relapsed during 1931-32.

Of thirty cases seen during 1931-32 in seven cases there was a history of similar attacks in previous years.

Treatment.—With the object of investigating the effect of treatment, the patients were divided into two batches, the one batch being treated and the other not. From humanitarian reasons however it was found advisable to give treatment to all the patients who showed at all marked signs of pellagra. Thus the value of the experiment was much diminished. All cases, both treated and untreated, recovered. In previous years the death rate was 25 per cent. In 1932 when all the more marked cases have been treated the death rate was nil; this appears to indicate that treatment is of considerable value, but the proof is incomplete for the cases seen during the last year have been on the whole of a less severe type than those seen in previous years. Whether the treatment prevented the development of severer forms is uncertain. We would therefore refrain from dogmatizing regarding the value of treatment for pellagra. The treatment given was based on that advocated by Goldberger. The ordinary diet, which consist of rice, *dāl* and *jawari*, was augmented by the addition of half a pound of meat a day. In addition powdered medicinal yeast 60 grains three times a day was given. Since all the cases were treated comparatively early and before the onset of severe gastro-intestinal symptoms, the treatment was tolerated well, but the severer cases seen in previous years would have been difficult or impossible to treat on these lines. In our experience early diagnosis is of vital importance as later on treatment by diet is extremely difficult, owing to gastro-intestinal symptoms making it impossible for the patient to take the prescribed diet.

Ætiology.—We can add little to our previous remarks about ætiology which is obscure.

PELLAGRA IN GUNTUR*

By T. K. RAMAN, M.D., D.T.M. (Bengal)

(From the District Headquarters Hospital, Guntur)

As far as I am aware no definite case of pellagra has been reported in Madras Presidency although the disease has been reported from other parts of India. In 1931, Lowe reported 40 cases of pellagra occurring in the patients undergoing treatment for leprosy from Dichpali (Hyderabad).

During the course of my four years' stay in Guntur four cases of pellagra have come to my notice :—

Case 1.—A Hindu male, aged 30, was admitted to hospital in September 1930 for chronic dyspepsia. On investigation, he was found to be of unsound mind, showing symptoms of delirium and occasionally of mania. On further examination, he showed a symmetrical rash on the dorsum of both upper and lower extremities which according to him was only of three months' duration. The margins were circumscribed and scaly patches distributed all over, which could be easily removed leaving a depigmented area underneath. His mouth showed ulcerative stomatitis. No further investigation was possible as he refused to be kept in hospital.

Case 2 (figure 1).—A Hindu female, aged 35, was admitted in February 1931 for general weakness,

Fig. 1.

anæmia, and a rash over both the upper and lower extremities. The rash, according to the history, was of seven years' duration starting from the dorsum of both

(Continued from previous column)

Pellagra is associated with ill-balanced diet, but this may be merely a predisposing cause to an infection. Leprosy seems to have little to do with the causation of pellagra. In our experience it is less common in the severer forms of skin leprosy with marked widespread infiltration of the skin than in the slighter nerve forms of leprosy in which there is frequently anhydrosis of the extremities.

* A résumé, prepared by the Editor, of a paper read before the Third Andhra Provincial Medical Conference held at Guntur in April 1933.

the upper and lower extremities extending high up and becoming more and more thick and scaly. The patient was gradually getting weaker and on admission she had secondary anaemia, acute glossitis, diarrhoea, and occasional passage of mucus in the stools; under the microscope the stools showed undigested fat and polymorphonuclear leucocytes, evidence of damage to the mucous membrane of the intestine. The blood showed the picture of secondary anaemia.

The patient died of extreme weakness and anaemia.

A post-mortem examination was made; the more important findings are as follows:—*Heart and pericardium.* Heart, weight—10 ounces; the ragged surface of the pericardium showed evidence of pericarditis; there was also dilatation; the muscle showed fatty degeneration. *Liver,* weight—34 ounces; fatty mottled liver; *microscopically,* the normal structure of the liver is almost completely lost and replaced by fatty tissue with here and there a few surviving degenerate liver cells. *Spleen,* weight—5 ounces; infarction present; *microscopically,* slight thickening of the capsule, atrophy of the endothelial tissue, slight increase of the reticular fibres, atrophy of the lymphoid tissue. *Kidneys,* weight—4½ ounces each; infarction of the right kidney; *microscopically,* marked fatty degeneration of the tubular epithelium; shedding of the epithelium of the convoluted tubules. *Small intestines,* slight atrophy of the mucous membrane; no ulceration or cellular infiltration. *Large intestines,* marked atrophy of the mucous membrane. *Skin and subcutaneous tissue:*—On tracing the skin from the healthy to the affected side the noticeable feature is a marked atrophy of the epidermis in its entire depth; the superficial keratinized layers are being shed. No overgrowth of the Malpighian layer is seen, nor is there any sclerosis of the vessels.

Case 3 (figure 2).—A Hindu boy, aged 14, admitted in December 1932 for anaemia and skin disease. This is the second attack of the skin disease; the last one which occurred exactly one year ago lasted for only two months and completely disappeared. The condition has recurred again during the course of the last two weeks. The anaemia is getting worse and the patches are extending. On admission, he showed evidence of secondary anaemia with hæmic murmurs, and occasional attacks of diarrhoea. *Skin lesions:*—Patches typical of pellagra appearing on the dorsal aspects of both upper and lower extremities, extending as high as the elbow

Fig. 2.

and the knee respectively. On investigating the diet, we found that he took rice—three ounces—three times a day, brinjals, cucumber and mutton once a week, eggs once a week, and dāl and maize occasionally. He eats no rice on the day he eats maize; he takes no milk, but takes butter-milk daily.

He was put on liver extract—8 ounces—daily, toddy, 6 ounces, and bread and milk. The symptoms gradually disappeared a month after admission.

Case 4 (figure 3).—A Mohammedan male, aged 20 years, a tailor by occupation, was admitted on 9th

Fig. 3.—Note the patch on the right side of the neck.

March, 1933. He came with a complaint of indigestion, loss of appetite, and soreness of the mouth and tongue. On investigation it was found that this was the second attack. The first attack was one year ago during the same season of the year. He had slight oedema of the legs, and skin lesions, typical of pellagra, on both hands and legs, and on both sides of the neck behind. The symptoms had disappeared in the course of a month by discarding rice diet and taking only milk, bread and fruits. The present attack appeared about two months ago. There was no oedema. Indigestion and loss of appetite were present from the onset. The lesion appeared first on the dorsum of both the hands and spread up to the elbow. A few days later symptoms appeared on the dorsum of the feet. The lesions on the neck appeared along with that of the hands. The patches are dark and scaly, can be peeled off from the skin and the outer margin of the patch is quite distinct, a characteristic which distinguishes it from ichthyosis which it closely simulates. He is a fairly well-nourished boy, very slightly anaemic; occasionally he gets attacks of stomatitis. The knee jerks are sluggish. On investigating the diet we found that he eats milled rice—four ounces—three times a day, meat once a week, vegetables—two ounces—daily, dāl, fish, butter-milk, and ghee, occasionally; he takes no milk and never eats maize. The patient was put on toddy, eight ounces a day, iron, arsenic and strychnine by mouth. The patches had completely disappeared by 27th March, 1933, but the symptoms started again on 31st March, 1933. A red hyperæmic patch appeared on the dorsum of the right hand and the right side of the neck. On 3rd April, 1933, the red induration had

turned to a dark, coppery-red colour. Next day it became darker, and three days later scaly patches appeared. In this case one was able to follow the course of the pellagra from the red congested area to the final stage of dark scaly patches with circumscribed areas.

Discussion

During the course of investigation of beri-beri in this district, I was surprised not to find any pellagra, a disease closely simulating beri-beri in its aetiology; both are vitamin-deficiency diseases. Although I was on the lookout for the disease I was only able to spot the four cases mentioned above, during the course of the last four years. The last case was accidentally spotted by me in the out-patient department, being treated as a case of indigestion and a condition of the skin. No doubt can exist as to diagnosis of the four cases described above. Case 1 illustrates the nervous complications arising in the course of pellagra. Case 2 has given us the full opportunity of studying the pathology and morbid anatomy of the disease. From cases 3 and 4, one was able to study the clinical aspect of the disease and the effect of vitamin B administration. Case 4 cannot be fully explained; the administration of the pellagra-preventing factor, though it produced rapid amelioration of symptoms, did not prevent the recurrence of the disease. In this case, evidence is produced against the theory that maize is the causative agent in the production of pellagra, since the patient has never taken maize at any time.

My thanks to Dr. T. Bhaskara Menon, M.D., M.R.C.P. (London), for the microscopic examination of the specimens.

ON THE INCIDENCE OF ARSENICAL DERMATITIS*

By H. K. CHAKRAVARTY, L.M.P.

Deputy Superintendent, Voluntary Venereal Hospital, Alipur, Calcutta

THE report covers a period of six years from 1927 to 1932, during which the total number of injections made was 3,914; during this period there were 15 cases of exfoliative dermatitis that could be attributed to arsenic injections. Novarsenobillon, sulfarsenol and thiosarmine were used; the number of cases treated with novarsenobillon was 449, with sulfarsenol 74, and with thiosarmine 50, and the respective number of injections given of each was 3,530, 468, and 600.

It is interesting to note that dermatitis occurred only in cases treated with the first-named drug.

From the above it will be seen that the cases in which the dermatitis occurred were few and

far between. If the incidence of dermatitis be so rare in hospital practice it must be more rare in private practice and there may be instances in which a general practitioner hardly comes across a case of arsenical dermatitis in his practice. It will, therefore, be worth while describing briefly the chief characters of the cutaneous affections that may occur under arsenical treatment.

Urticaria is common; it may appear during or immediately after injection, but generally disappears within a few hours. Some patients complain of itching of some particular part of the body after each injection and this itching may be a symptom of intolerance. In some cases after a number of injections have been made erythema may appear, the rash of which sometimes remains patchy and resembles seborrhoeic eczema. Hyperkeratosis of the palmar and plantar surfaces and atrophy of the nails, toxic alopecia of the areata type, herpes zoster due to inflammation of posterior root ganglia, and herpes simplex involving the vulva and lips, will occasionally occur. Acne-vulgaris boils and carbuncles are aggravated by arsenic or may appear for the first time under the influence of the drug, and there is occasionally a focal reaction at the site of an old chancre.

The most distressing condition, however, is exfoliative dermatitis. The eruptions appear on the inner aspect of the arms, forearms, thighs, lower part of abdomen, as well as on the face, and in bad cases may extend over the whole body within 72 hours. The first appearance is like a measles rash with severe itching, which is at first limited to certain areas but rapidly extends all over the body, becomes confluent, and in a few days forms into vesicles and pustules. The whole body is swollen, the face oedematous and disfigured, the eyes cannot be opened and there may be conjunctivitis. This first stage is called the dry stage. In this stage there is intense itching all over the body. There is a rise of temperature, usually throughout the disease, both in the dry and the weeping stages. After a week or so the weeping stage begins when the vesicles and pustules are ruptured and discharging ulcers are formed. In the worst cases the cuticle comes off like a glove from the hands and feet. There is severe burning pain all over the body, and the patients want to dip the whole body into water. After the separation of the cuticle, the cutis vera is exposed and in places ulcers form and extend deep down to the muscle. Septic complications may start, leading to multiple boils all over the body, or cellulitis. The patient often becomes extremely prostrated, bed-sores form, and toxæmia, broncho-pneumonia or intestinal hæmorrhage are not uncommon terminal conditions.

Recovery is always slow and convalescence protracted. One peculiarity of arsenic poisoning is that if one organ is involved to a serious extent, the other vital organs are generally

* Rearranged by Editor.

spared. In extensive exfoliative dermatitis, the liver and kidneys may be spared, and in cases in which the liver is badly involved, the kidneys and heart may escape altogether.

The following table gives the incidence of dermatitis, year by year.

NOVARSENOBILLON					SULFARSENOL AND THIOSARMIN		
Year	Number of cases	Number of injections	Incidence of dermatitis	Percentage of dermatitis	Number of cases	Number of injections	Incidence of dermatitis
1927	104	770	4	3.84	2	24	Nil
1928	103	824	4	3.88	6	48	"
1929	90	720	2	2.22	12	72	"
1930	65	520	3	4.61	10	60	"
1931	62	496	2	3.23	30	180	"
1932	25	200	Nil	Nil	64	684	"
TOTAL	449	3,530	15	..	124	1,068	Nil

The following table gives the time of appearance of the dermatitis in relation to the number of doses and the total dose of the arsenical given.

Number of cases	Number of injections prior to onset	Total dose prior to onset in grammes
1	1	0.3
6	3	0.9
6	4	1.2
1	6	2.1
1	7	2.55

All our patients being women they get the first four injections of 0.3 gm. each and the next four injections of 0.45 gm. each, making a total of 3 grammes. They also get a course of bismuth or mercury injections along with the arsenic treatment.

From the above it is evident that the arsenical dermatitis may be due to natural hypersensitiveness to arsenic, as in one of these cases it occurred after one injection only. Undoubtedly in the majority of cases the skin lesions are due to the cumulative toxic effects and these are due to injury to the important organs concerned, namely the liver and kidneys, by the chronic pathological changes caused by the *Spirochæta pallida* in some cases, by bacterial or other diseases in others, and by the administration of mercury in probably not a few. In two cases of our series in which mercury (4 c.cm. of mercurisol) was injected along with the arsenic, a very severe form of dermatitis appeared after the injection; both of these patients had albuminuria.

On the night before the injection the patients were given a light diet, they were allowed no food in the morning prior to the injection and for the rest of the day they were given only

barley water and milk. A dose of glucose was given with alkali an hour before the injection to protect the liver cells. A saline purge was given the previous night and again on the following morning to help excretion of arsenic. Patients were kept in bed on the day of the

injection. In cases of accidental extravasation of novarsenobillon solution into the subcutaneous tissues, we have got very good results by immediately injecting sodium thiosulphate solution subcutaneously in the infiltrated zone. This immediately lessens the local irritation, the patient is relieved of the extreme pain, and after-effects are obviated.

In 1932 at the suggestion of Lieut.-Colonel Denham-White, 3 c.cm. of 10 per cent. sodium thiosulphate solution was injected after the fourth dose of novarsenobillon in 25 cases; in none of these cases has dermatitis occurred.

Treatment for dermatitis.—The usual treatment was followed; patients were put to bed and kept at absolute rest; liquid carbohydrate diet, such as barley water and glucose, and milk were given; protein and fat were restricted; calamine lotion was applied externally in the dry stage to allay itching; an alkaline mixture containing potassium citrate, potassium bicarbonate, and urotropine was given orally several times a day; saline purgatives were given daily to help the excretion of the arsenic; ichthyol, grains ii, in pill form, was given twice a day; and 10 per cent sodium thiosulphate solution was given intravenously or intramuscularly every alternate day or every day up to 4 c.cm. at a time, for five or six injections, or until the progress of the disease was checked. In the weeping stage ichthyol in arachis oil was applied externally over the cracked and painful areas. In prostrated conditions stimulants were administered, the patient was protected from cold, and the ulcers kept clean. After recovery no further arsenic treatment was given for at least a year.

Some illustrating case notes are appended below :—

(1) K., Hindu female, aged 30 years, admitted on 27th October, 1930. Wassermann reaction strongly positive. She was treated with novarsenobillon and

mercurosol, alternately. After the third injection the reactionary fever had persisted for three days, instead of subsiding within 24 hours as usually happens. When the next dose of one c.cm. mercurosol was injected the temperature rose again for one day. This temperature started with a rigor and was thought to be malaria, but no parasites were detected on blood examination. Two weeks after the third injection the fourth dose of novarsenobillon was given intravenously; two days later an itching erythematous rash appeared on the chest and thighs, there was swelling of the face, and pain all over the body. After ten days pustules started to develop at the roots of hairs and there was a slight rise of temperature. The skin began to scale off leaving discharging ulcers.

The dermatitis persisted for one month during which time five injections of thiosulphate were given. The itching sensation continued for a month more.

(2) S., Hindu female, aged 23 years, admitted on 12th June, 1931. Wassermann reaction strongly positive. She was treated with novarsenobillon and bismostab, given alternately. Seven days after the third injection of novarsenobillon (0.3 gramme) she developed intense itching; sodium thiosulphate was immediately injected intravenously. The itching disappeared and novarsenobillon was resumed after two weeks, but each injection was preceded by an injection of sodium thiosulphate. Bismostab was also continued. She had five more injections of novarsenobillon, one of 0.3 gramme and four of 0.45 gramme, each preceded by sodium thiosulphate; she developed no further symptoms of intolerance. She was discharged cured on 4th October, 1931, with Wassermann reaction negative.

(3) G., Hindu female, aged 25 years, admitted on 9th March, 1931. Wassermann reaction negative at first, but after a provocative injection of novarsenobillon of 0.3 gramme it was moderately positive. She was then treated with novarsenobillon and mercurosol, 1 c.cm., alternately. She was given four injections of 0.3 gramme novarsenobillon and one of 0.45 gramme. After the fifth injection of novarsenobillon she continued to have a daily rise of temperature; this ranged from 100° to 103°F. On the third day dermatitis appeared over the face, axillæ, forearms and thighs. The urine was free from albumen, though scanty in amount; the motions were loose. Her face was swollen so much that she could not open her eyes, and she had conjunctivitis. Her skin came off in flakes leaving profusely discharging ulcers. She then developed multiple boils all over the body, bed-sores on her back, buttock, and heels, and her condition was precarious.

The usual treatment was given; she received six injections of sodium thiosulphate of 2 c.cm. each, intramuscularly, as the bend of the elbow was involved in dermatitis intravenous injection was not possible. Her condition became very bad and she was given brandy, digitalis, and strychnine. She recovered, and was discharged cured after eight weeks.

A PLEA FOR COLLAPSE THERAPY IN THE EARLY STAGES OF PULMONARY TUBERCULOSIS*

By P. T. PATEL, M.D. (Lond.), M.R.C.P. (Lond.),
B.T.M. & H. (Cantab.), F.C.P.S. (Bom.)

Medical Superintendent, City Fever Hospitals, Arthur Road and Maratha Tuberculosis Hospitals, Honorary Physician, King Edward VII Memorial Hospital, Parel, Bombay

THE medical profession in this country has been slow to take advantage of one of the most important recent advances in the treatment of

pulmonary tuberculosis. Doctors are liable to rely too much on remedies such as creosote, cod-liver oil, calcium and the various gold preparations, and, without considering sufficiently the economic aspect, to advise their patients to go away for a change of air or to a sanatorium. The fundamental measure in the treatment of tuberculosis should be rest of the affected part; other methods can then be employed to raise the resistance of the body as a whole against the infection. The only way that the lung can be given rest is by causing collapse of the whole or part of the lung. The best results are obtained in early cases of tuberculosis, and therefore our aim should be the early diagnosis of the lesions and the adoption of collapse therapy without delay.

The methods by which this form of treatment can be applied are artificial pneumothorax, phrenicotomy and phrenic evulsion, apicolysis (i.e., paraffin compression), and thoracoplasty. Of these the first mentioned is the simplest and can be performed by the average practitioner in any hospital or dispensary.

Phrenic evulsion is also a simple operation and can be undertaken under a local anæsthetic; it is very often a useful adjunct to the pneumothorax treatment, especially in cases in which there are basal lesions with adhesions, but it is also adopted as an independent form of treatment. Phrenic evulsion causes paralysis of the diaphragm on one side, with the subsequent limiting of the movements of the lung.

Apicolysis, the name given to the operation of injecting paraffin to cause collapse of the apex of the lung, and thoracoplasty are both more formidable operations which should only be undertaken by experienced surgeons in well-equipped hospitals.

Indications for artificial pneumothorax.—It has been said that pneumothorax therapy is not necessary in early cases when the disease is still curable by sanatorium and other methods of treatment, but the condition is seldom diagnosed at this stage in this country. On the other hand no case is too advanced, provided it is one-sided and there are no adhesions which would prevent the compression of the lung. The essential factor is the softness of the lung which can be judged by clinical and x-ray examinations. There is no reason why a bilateral operation should not be done as long as there is healthy lung tissue sufficient for respiratory exchange.

Any early active case of pulmonary tuberculosis, either with one or both lungs affected, is suitable for this line of treatment. The persistence of any of the following symptoms and signs is an indication of 'activity':—rise of temperature, hæmoptysis, loss of weight, tubercle bacilli in the sputum, toxæmia, general failing of health and persistent catarrhal signs in the lungs, and persistent pleural effusion. In

* A résumé, prepared by the Editor, of a paper read before the Medical Research Section of the Indian Science Congress, Bangalore, 1932.

the last instance gas replacement after aspiration of fluid is very successful.

Ambulatory pneumothorax.—Patients who are not seriously ill can be treated even as out-patients and after the injection can be sent home to return at stated intervals for refills. Of course they must stay in bed at the beginning, and have fresh air, a good nourishing diet, and tonics. We have many cases taking treatment like this after the first injection and getting on well.

The contraindications are extensive bilateral disease with cavitation, chronic fibroid disease, tuberculous enteritis, asthma, and severe constitutional disturbances.

Apparatus.—An elaborate apparatus is unnecessary, and one can be improvised on the simple principle of replacement of air by water

As regards technique of the operation, the amount of gas to be filled in and the intervals to be observed, I would refer the reader to my article in the *Indian Medical Gazette* of December 1927.* A practical acquaintance with all the details is, however, very necessary, and can only be obtained by attending the hospitals and clinics where this therapy is practised.

Illustrative cases

A bilateral case.—The patient, a man, aged 20, was admitted on 12th July for evening rise of temperature, cough with expectoration, and loss of weight. Clinical and x-ray examination showed signs in both the lungs, and sputum showed tubercle bacilli. Artificial pneumothorax was started first on the right side, and then on the left side. His temperature came under control after about a month's treatment and remained normal till he was discharged. He showed definite increase in weight by 14 pounds, and improved in all respects. He

Temperature chart in the bilateral case.

Temperature chart in the unilateral case.

from one bottle to another; to avoid the water manometer which is troublesome and unnecessarily increases the size of the apparatus, a portable apparatus with an aneroid manometer, like that made by Bullitte of Paris for Professor Mainini, is most suitable and cheap.

is taking ambulatory treatment now. He had a bad fistula in ano which also is healing up after operation.

*The reader is also referred to our Current Topics section. We have here reproduced a chapter on this subject from a recently-published book.

Unilateral case.—The patient, a woman, aged 28, was admitted on 24th July for evening rise of temperature, loss of weight, and cough with purulent expectoration. Clinical and x-ray examination showed signs of tuberculosis in the right side of the chest; tubercle bacilli were found in the sputum. Weight on admission was 88 pounds. Artificial pneumothorax was performed on the right side. The temperature came down after 25 days, and remained normal until she was discharged. There was definite increase in weight to 90 pounds. Symptoms were much relieved. The patient is still under treatment. Further details can be seen from the table and the temperature chart.

A table showing the amounts of air injected and the pressure before and after the injection and a temperature chart for each of these cases are given.

The collapse therapy can be carried out in any climate provided the patient is under constant observation and takes ordinary measures of rest, open air, sufficient nourishment, etc. Climate by itself has no special influence in the cure of pulmonary tuberculosis compared to the early control by collapse therapy, and from experience of cases treated in Bombay for some years I quite agree with Knoff (1931) that there is no specific climate for tuberculosis; if I had to choose between having a patient under special medical supervision with mental and physical rest in his home climate, or sending him even to an 'ideal' climate where he would merely do as he pleased, I would prefer the former, believing he would have a better chance for recovery.

Results

Unilateral cases.—Out of the 25 cases that have come under my treatment during the last two years, 19 cases are practically cured; x-ray examinations and physical signs and absence of tubercle bacilli indicate that the lesions are healed, no tubercle bacilli can be found in their sputum, and they are mostly following their normal vocations.

Bilateral cases.—The results here are not so successful, but eight out of twelve patients have improved to the extent indicated above.

A FEW OBSERVATIONS ON THE PHARMACOLOGY AND THERAPEUTICS OF MUSCLE EXTRACT

By P. GANGULI, L.M.S., D.T.M.

Additional Physician, Medical College Hospitals, Calcutta

MUSCLE extract has for some time been used in the skin department of the Calcutta School of Tropical Medicine in the treatment of certain skin diseases, and Lieut.-Colonel H. W. Acton, the director of the school, was kind enough to supply me with muscle extract made in the chemical department of the school. A few cases of grave vascular and kidney diseases were treated with this muscle extract and the results were so striking that it encouraged me to proceed with further investigation of its action in other cases.

Preparation of the muscle extract

Bullock's heart muscle was used for the preparation of the extract as recommended by

Drury and Szent-Györgyi (1929). The heart muscle was finely minced and then treated with 5 per cent trichlor-acetic acid in proportion of 1 c.cm. of the dilute acid to 1 gramme of the muscle and allowed to stand overnight. The fluid was pressed out and filtered. The filtrate was then neutralized.

When larger quantities of muscle extract had to be prepared, the muscle was treated with 1 per cent solution of trichlor-acetic acid and kept for half an hour with occasional stirring; the mixture was then heated up to 90°C. and subsequently cooled. The fluid was pressed out, filtered, neutralized, and standardized.

My thanks are due to Mr. A. C. Roy, who actually prepared the muscle extract, for the short description of the method of preparation that has been given above.

The hydrogen-ion concentration of the muscle extract after neutralization should be slightly on the acid side, viz, pH 6.8 to 6.9. The slight acidity causes intense swelling and pain, when the drug is injected subcutaneously. It should always be injected intramuscularly, so as to make it potent by de-amination in contact with muscle tissues, resulting in the formation of ammonia therein, which may be one of the factors in imparting the sensation of well-being which the patients usually experience after muscle extract is given.

Thrombo-angitis obliterans

The practical application of muscle extract as a vaso-dilator was recorded by Schwartzmann (1931) who used it in thrombo-angitis obliterans and allied conditions, with satisfactory results.

Two cases of thrombo-angitis obliterans were treated in the wards of the Medical College Hospital. One of them was a child who arrived too late, but the other was treated successfully with muscle extract.

Case 1.—Hindu male child, aged 1 year, was admitted on 18th May, 1932, for treatment of thrombo-angitis obliterans and gangrene of the toes. This case was complicated with ileus. The patient arrived too late, as only two doses of muscle extract could be given, and the child died of ileus on the third day after admission.

Case 2.—Hindu male, aged 22 years, was admitted for treatment of fever of 6 days' duration, temperature on admission being 104°F. On examination, bronchopneumonic patches were found in the lungs. His urine contained a large quantity of albumen and gave a positive reaction with dimethyl-para-amino-benzaldehyde solution. The case was diagnosed as influenza. The fever came down to normal on 27th June, but on the same evening a swelling of the lower third of his left leg was observed which quickly extended to the thigh within a day. On examination no pulsation could be felt over his dorsalis pedis and posterior tibial arteries. The left toes were cold. The Wassermann reaction of his serum was negative. Injection of muscle extract was commenced on 28th June. On 30th June, the swelling of the leg went down but some dark ischæmic spots appeared on the left foot and leg, the most marked being on the dorsum of the left half of the left little toe and a big patch, 1½ inches by 1 inch, on the postero-lateral aspect of the left knee; these

patches became hyperæsthetic. A feeble pulsation of the dorsalis pedis artery gradually returned. The patient received 20 injections of muscle extract up to 27th July, in 1 c.cm. doses. Some of the patches, which turned black, gradually disappeared, but three patches on the inner aspect of the knee joint became ulcerated after a period of burning sensation. On 3rd August, a third course of muscle extract was begun as the ulcers remained dormant and showed no signs of healing. These ulcers then quickly granulated and healed up. The patient was discharged cured on 28th September.

Arterio-sclerosis

Schwartzmann (1931) reported satisfactory results in fourteen cases of intermittent claudication due to arterio-sclerosis. Two cases of advanced arterio-sclerosis were treated with muscle extract in my wards, but the results were not satisfactory.

It is difficult to understand how the muscle extract could have any beneficial effect on advanced cases with calcified atheromatous arteries. In both my cases, the muscle extract produced embarrassment of the overloaded heart. In early cases, however, muscle extract may produce a beneficial effect by relaxation of the spasm of the vasa vasorum of the affected arteries.

Angina pectoris

The vaso-dilator action of the muscle extract was suggested by its beneficial action in relieving distress and pain in angina pectoris. Schwartzmann (1931) recorded wonderful results in 9 out of 11 cases with a history of coronary thrombosis and myocardial disease. The action is attributed to vaso-dilator action by overcoming the vascular spasm in that disease. The spasm is supposed to be due to the effect of pressor substances generated in excess or to the balance of pressor or depressor substances being upset. The pain is due to ischæmia of the heart muscle which is relieved by vaso-dilatation. In case 2, reported above, the pain and hyperæsthesia was due to the ischæmic condition of the patches of skin involved.

Nephro-sclerosis

Muscle extract exerts fibrolytic action in pathological fibrosis of internal organs. It cannot be expected that it should have any such action on physiological scar tissues. Acton used this substance as a fibrolytic agent in the treatment of elephantiasis, scleroderma, etc., in the School of Tropical Medicine. In many cases of elephantiasis remarkable diminution in the size of the affected limbs was noted. The fibrolytic action is probably due to the increased blood supply of the affected organs and to the increased number of phagocytic leucocytes coming in contact with fibrous connective tissues. This action of the muscle extract has been utilized in the treatment of nephro-sclerosis, mitral stenosis, cirrhosis of the liver and various other diseases associated with fibrosis

in my wards. The following are some of the illustrative cases:—

Case 3.—Hindu female, aged 17 years, was admitted on 10th November, 1931, with signs of general anasarca and fever of 5 months' duration. Physical examination revealed enlarged liver, tenderness in the right iliac region, and slight tachycardia. The urine was scanty and showed on examination copious albumen (0.4 per cent), hyaline and granular casts, and a few red blood cells.

She was put on Epstein's diet and urea. There followed an increase in the quantity of urine and diminution of oedema all over. The fever was found to be due to malaria (*Plasmodium malaric*) and was checked by atebirin. The biochemical examinations now showed the following results:—Blood cholesterol 0.01 per cent, blood chloride 0.544 per cent, blood urea 0.028 per cent, blood non-protein nitrogen 0.056 per cent, and urinary albumin 0.2 per cent. The urea-concentration test showed defective elimination of urea, viz. 0.5 per cent in the third sample passed two hours after the dose of urea. There was, however, no further improvement for some time. The intramuscular injections of muscle extract were commenced from 10th January, 1932. After seven daily injections of muscle extract, the elimination of nitrogenous metabolic products increased and the urea-concentration test showed excretion of 1.2 per cent of urea in the third sample passed two hours after the load of urea. There was however no further improvement, although seven more injections of muscle extract were given. The search for septic foci revealed salpingitis of the left side, for which the patient was treated with injections of milk. Each injection of milk was followed by transient reappearance of oedema and this was attributed to transient exacerbation of nephrosis due to increased elimination of toxins from the septic foci. During this time excretion of urea in the urea-concentration tests fluctuated between 0.9 and 1.2 per cent. The infected tonsils were then removed. A further exhibition of muscle extract increased the elimination of urea to 1.5 per cent after which it remained stationary. The patient still suffered from recurring temporary exacerbation of chronic nephrosis. When the patient was discharged on 25th May, she was free from oedema, but the elimination of urea was only 1.5 per cent.

This patient was suffering from chronic nephrosis, with secondary nephro-sclerosis. The toxin from the septic foci was keeping up chronic nephrosis. The removal of septic foci ameliorated her condition, but left the renal tubules in an allergic state; this allowed an exacerbation of the nephrosis on the slightest provocation. The fibrolytic action of the muscle extract was responsible for increased elimination of nitrogenous metabolic products.

Case 4.—Hindu male, aged 26 years, was admitted on 5th April for treatment of ascites and general anasarca of two and a half years' duration. The case was diagnosed as chronic nephrosis with secondary nephro-sclerosis. The urea-concentration test showed elimination of 1.3 per cent urea in the third sample. The dye test showed 35 per cent elimination in two hours. He was anæmic, his blood count showing 3,210,000 red blood cells, and 5,616 white blood cells per cubic millimetre, and hæmoglobin 60 per cent. Treatment with muscle extract was begun on 13th August, and ten injections were finished on 27th August. The urea-concentration test showed 1.6 per cent of urea on 27th August. Euphyllin was given twice daily *per os*. The patient's condition went on improving. When he was discharged on 5th September, he was free from oedema and ascites and showed normal elimination of urea.

Case 5.—Hindu female, aged 36 years, complained of intense headache for 6 months, which was thought to

be neuralgic. Her blood pressure was high; systolic pressure was 160 mm. Hg. and diastolic 100 mm. Her elimination of urea was 1.6 two hours after the load of urea was given. Ten injections of muscle extract increased the elimination of urea to 2 per cent and reduced the systolic and diastolic pressures to 120 and 90 mm. Hg., respectively, but the headache remained the same as before.

Case 6.—Hindu male, aged 60 years, was admitted on 17th August, for treatment of oedema of the lower extremities, scrotum, abdomen and hands, of 8 months' duration. His urine contained 0.08 per cent albumen. The urea-concentration test showed elimination of urea only 1.15 per cent in the third sample drawn two hours after the urea load. Blood urea was 0.05 per cent.

Treatment with muscle extract was commenced from 23rd August, but it had to be stopped as the patient got an attack of influenza on 26th August. His temperature rose up to 103° and came down to normal on 30th August. Five more injections of muscle extract were given from 1st to 5th November. He was getting alkaline mixture all this time. When the patient was discharged on 13th September his urine was free from albumen, his elimination of urea was normal, his blood urea was 0.18 per cent and total non-protein nitrogen 0.28 per cent.

High blood pressure

It was seen in case 5, that along with the restoration of the normal functions of the kidneys, there was certain amount of reduction of high systolic and diastolic blood pressure. In the following two cases of high blood pressure the exhibition of muscle extract gave different results. In one case, the ætiological factor was the same as that of case 5, but in the other it was due to dysfunction of the endocrine system. The lowering of the high blood pressure in the latter case by muscle extract was due to relieving the chronic spasm of the peripheral arterioles which developed as a result of reaction to toxic bases or pressor endocrine substances circulating in the blood.

Case 7.—Hindu male, aged 45 years, was admitted on 18th February for treatment of high blood pressure. His principal complaints were giddiness and sleeplessness for over a month, pain in the thigh for four years, scanty urine and constipation. He had fever 8 years ago and swelling of the knee joints which started four years ago and kept on recurring at frequent intervals. The patient was very weak and suffered from pyorrhœa alveolaris. His systolic and diastolic pressures were 215 and 115 mm. Hg. respectively. His urine contained albumen and showed a few granular casts and pus cells. His blood urea was 0.06 per cent, non-protein nitrogen 0.977 per cent and cholesterol 256 mgm. per cent. The Wassermann reaction was negative. The urea-concentration test showed elimination of urea to be 1.6 per cent in the third sample.

After eight daily injections of muscle extract in 0.5 c.c.m. doses, all the complaints showed signs of amelioration; his systolic blood pressure came down to 135 mm. Hg. Biochemical findings of the blood were as follows:—Blood urea 0.04 per cent, non-protein nitrogen 0.056 per cent, cholesterol 130 mgm. per cent, and phosphate 0.0012 per cent. The muscle extract had to be discontinued owing to failure of supply, during which the systolic blood pressure rose to 170 mm. Hg., but again went down on resuming the treatment with muscle extract. He got 30 injections altogether after which his condition returned to normal; his urine became free from albumen; on 29th March his urea-concentration test showed normal elimination of urea; and his systolic and diastolic blood pressures were 130 and 75 mm. Hg. respectively. The patient left the hospital on 1st April free from all complaints.

It appears that the high blood pressure disappeared in this case with the removal of its cause, *viz.* nephro-sclerosis. In the following case of hyperpiesia with intermittent claudication and in which the kidneys were normally functioning, the muscle extract exerted only a temporary effect.

Case 8.—Hindu male, aged 36 years, was admitted on 26th May for treatment of hemiplegia. The patient gave a history of a sudden attack of unconsciousness for a few hours; on regaining consciousness he found that both the extremities of his left side were paralysed. On admission, his systolic and diastolic blood pressures were found to be 195 and 100 mm. Hg. respectively. His urine did not show any abnormal constituent. The urea-concentration test showed normal elimination of urea. The radial and other palpable arteries were soft and elastic, and no arterio-sclerotic changes were found in the retina. The case was diagnosed as hyperpiesia. Lumbar puncture showed a normal cerebrospinal fluid. The hemiplegia was attributed to intermittent claudication of a branch of the right lenticulostriate artery.

The injection of muscle extract was commenced on 2nd June. Hemiplegia disappeared quickly, and his systolic blood pressure went down to 140 mm. Hg. When the patient was discharged, he was free from all complaints, but his blood pressure was 160 mm. Hg.

Intermittent claudication

The following case of intermittent claudication showed almost a similar picture:—

Case 9.—Hindu male, aged 50 years, was admitted on 7th October for treatment of hemiplegia of the right side. He was a railway station-master and had sometimes to work on signals with his right hand. Occasionally, he used to experience sudden spasm of the right hand, while working the signals, and was compelled to stop work for a moment. Sometimes at night he used to experience similar spasms and difficulty of stretching his right leg. He had been suffering from these complaints for the last five years. He also gave a history of attacks of malarial fever off and on. A fortnight before his present illness he suffered from dysentery, with 10 or 12 motions a day. On 1st October he was going to his bathroom at 2 p.m., when he suddenly felt that he could not move his right hand and leg, and his speech became blurred. He had to be carried to his bed.

On admission, there was paralysis of the face and right extremities, which were soft and flaccid. The deep and superficial reflexes were present but sluggish. There was flexor response of the plantar reflex. The sensations were intact. His systolic and diastolic blood pressures were 170 and 100 mm. Hg. respectively. Urea-concentration test showed defective elimination of urea, *viz.* 0.8 per cent only in the third sample passed two hours after the load of urea was given. The case was diagnosed as nephro-sclerosis and the paralytic symptoms were assumed to be due to intermittent claudication of a branch of left lenticulostriate artery. Treatment with muscle extract was commenced from 12th October. On 20th October the systolic and diastolic pressures came down to 125 and 75 mm. Hg. respectively. The patient quickly got rid of his paralytic symptoms, the order of disappearance being face, hands and legs.

It will be apparent from a study of cases 5, 7, 8 and 9 that exhibition of muscle extract produced lasting benefit in high blood pressure of nephro-sclerotic patients, but only a temporary beneficial effect in hyperpiesia due to endocrine disorders, and had no effect in reducing blood pressure in advanced arterio-sclerosis. It may possibly be useful in early cases of

arterio-sclerosis, as claimed by Schwartzmann (1831), it probably acting by relieving the spasm of the vasa vasorum and thus ensuring the increased blood supply to the muscular coat of the arteries. The beneficial effect in nephro-sclerosis may reasonably be attributed to the fibrolytic action of the muscle extract.

Mitral stenosis

The fibrolytic action of muscle extract was taken advantage of in the treatment of the following progressive cases of mitral stenosis in which a lasting amelioration of symptoms was achieved. It was given with the idea of stopping the progress of contraction of fibrous scars in the mitral valve:

Case 10.—Hindu female, aged 16 years, was admitted on 4th January, complaining of dyspnoea and palpitations on the slightest exertion, cough, headache, and giddiness. She gave a history of rheumatic fever, while she was a child of 8 years old. Physical examination showed that she was suffering from mitral stenosis. This was confirmed by orthographic mitral configuration, teloradiographic curved impression of the œsophagus caused by hypertrophic left auricle, and electrocardiographic tracings showing broadened and notched 'P' deflections. The patient was put on digitalis and there was some improvement, which however remained stationary. Injections of muscle extract were then given and after receiving two doses, the patient became cheerful and felt better. The complaints quickly disappeared during further injections of muscle extract and administration of digitalis. The patient received ten injections of muscle extract in all, after which she was put to graduated exercise. She left the hospital with vastly improved exercise-tolerance.

Case 11.—Hindu female, aged 22 years, was admitted on 5th January with symptoms of nausea, indigestion, dyspnoea, cyanosis, and expectoration of sanious and frothy sputum. Physical examination revealed signs of aortic incompetence and mitral stenosis. An orthogram showed mitralized aortic configuration and greatly hypertrophied left ventricle. Teloradiographic impression of the œsophagus showed hypertrophy of the left auricle. The Wassermann test was negative. After relief had been obtained from blood-letting and rest, she was given 10 injections of muscle extract. She improved very rapidly. Graduated exercise was then given, and she left the hospital with greatly improved exercise-tolerance on 4th March.

Case 12.—Hindu male, aged 13 years, was admitted on 2nd February with complaints of palpitation of the heart and dyspnoea on slight exertion, for the last three years, after an attack of rheumatic fever. His condition had become gradually worse during the last three months. The case was diagnosed as one of mitral stenosis. Blood pressure was 100/70 mm. Hg. An electrocardiogram showed notched 'P' deflection, low voltage 'R' in all the leads, and less filling of the ventricles. Teloradiographic curvature of the œsophagus was very marked owing to hypertrophy of the left auricle.

Injection of muscle extract was begun on 8th February, and continued in 0.5 c.cm. doses for 10 days. The patient felt more comfortable after each injection. His pulse rate, which was 109 per minute, came down very gradually. However, he developed slight œdema of the legs after the sixth injection, which disappeared after two days. He could not tolerate digitalis at the time of his admission, but when ten injections of muscle extract were finished, he tolerated it very well. After ten days' rest, he was given a second course of muscle extract for ten days. An electrocardiographic tracing showed inverted 'T' wave in the second lead, which ordinarily indicated grave myocardial damage; the

patient however was improving and showed no signs of myocardial weakness or exhaustion. After a few days' rest, a third course of muscle extract was given. An electrocardiographic tracing was again taken and this time the second lead did not show any inverted 'T'

Fig. 1.—(Electrocardiograph taken before exhibition of muscle extract). Rate of heart beat—122 per minute (tachycardia). 'P' notched in all the leads. 'R' low voltage in lead I.

Fig. 2.—(Electrocardiograph taken after two courses of muscle extract). Rate of heart beat—93 per minute. 'P' notched in all the leads. 'R' low voltage in lead I, and inverted in lead III. 'T' inverted in leads II and III.

wave, nor any other abnormality except a notched 'P' deflection due to mitral stenosis. He was discharged on 9th April, with advice to work within the limits of

his exercise-tolerance. I have kept in touch with this patient; he is doing well.

Fig. 3.—(The same case after the third course of muscle extract). Rate of heart beat—88 per minute. 'P' notched and prominent in all the leads. 'R' low voltage but higher than those of figures 1 and 2 in lead I. 'T' positive and prominent in lead II.

Case 13.—Hindu male child, aged 9 years, was admitted on 30th March for treatment of orthopnoea, dry cough, and oedema of the legs and face. He suffered from rheumatic fever two years ago. He had begun to get dyspnoea on exertion since January last; it had gradually become worse. There was a certain amount of bulging of the chest wall over the left precordial region. Teloradiographic impression of the oesophagus showed curvature due to hypertrophy of the left auricle. The case was diagnosed as one of mitral stenosis. An orthogram showed mitral configuration. An electrocardiogram showed tachycardia with broad and notched 'P' wave.

The patient was given Guy's diuretic pill, and magnesium sulphate, and then put on digitalis until the oedema disappeared and dyspnoea was much less. On 10th April injection of muscle extract was commenced and continued for ten days. The patient became cheerful, felt better, and actually wanted to have more injections. On 15th April ova of *Ascaris lumbricoides* were detected in his stool and several worms were passed with the stools after the administration of santonin. On 2nd May the patient took unauthorized walking exercise in the corridor, as a result of which he again became dyspnoeic and suffered from nausea and vomiting. The rate of heart beat went up to 149 per minute. His vomiting was checked by dilute hydrocyanic acid and the rate of heart beat went down after administration of pandigal. A second course of muscle extract was given, and then a third course. He began to make an all-round improvement. He was put to graduated exercises and his exercise-tolerance improved quickly. His weight, which was 44½ lbs. on admission, increased to 64½ lbs. at the time of his discharge on 1st August.

Case 14.—Hindu female child, aged 9 years, was admitted on 9th August for treatment of palpitation, breathlessness on slight exertion, slight swelling of both knee joints and elbows, and pain in the wrists and small joints of the hands. The patient gave a history of rheumatic fever two years ago. Physical signs showed

that she was suffering from mitral stenosis. An orthogram showed typical mitral configuration and radiogram showed curvature of the oesophageal shadow. She was very anæmic, 2,000,000 red blood cells per c.mm. of blood. Her pulse rate was 136 and respiration 34 per minute.

The patient was given two courses of injections with muscle extract. Her complaints disappeared quickly and the pulse rate came down to normal. She was then put on to graduated exercise. Her exercise-tolerance was increased when she was discharged from the hospital on 30th September.

In all these five cases of mitral stenosis, there appeared a lasting amelioration of symptoms of the disease which could reasonably be explained from arrest of contraction and fibrolysis of the scar of the mitral valves. It appears that even physiological scar tissues can be dissolved to a certain extent. This suggestion has been corroborated by observations that in all these five cases of mitral stenosis, there was not only increase of exercise-tolerance but the presystolic thrills became much softer after treatment with muscle extract.

Banti's disease

The muscle extract was tried in the following cases of Bengal splenomegaly (Banti's disease) with the idea of stopping the progress of cirrhosis of the liver which is associated with this disease. The ideal treatment is supposed to be the removal of spleen. De (1932) considers that the cirrhosis of the liver in Bengal splenomegaly is of the multilobular type associated with excessive increase of the connective tissue in the trabeculae, exerting pressure on the radicles of the portal veins and causing ascites. When once this stage has been reached, surgical treatment is of little avail. Again, extensive adhesions of the spleen, a sequel of perisplenitis, makes the removal of the spleen a dangerous operation. Severe anæmia is regarded as a contraindication to operation. It was in these inoperable cases of splenomegaly that muscle extract was tried as an adjunct to deep x-ray therapy of the spleen, with the idea of effecting fibrolysis, allowing the liver cells some time to regenerate and thereby regain some of their lost functions. In one of the following two cases where muscle extract was tried, cirrhosis of the liver with ascites had already supervened, and in the other anæmia was so profound that surgeons would not operate :

Case 15.—Hindu female, aged 20 years, was admitted on 29th February with fever, swelling of the abdomen, anæmia and palpitations. The patient had had two children, the last being born two years ago. She had suffered from hæmorrhage from the uterus for three months. Later, she was attacked with dysentery with 20 to 30 stools a day. She then got swelling of the whole body which gradually subsided, but the ascites persisted. She suffered from frequent attacks of fever and had had no periods since her menorrhagia stopped, that is, for the last year and a half. She was extremely anæmic, erythrocytes being only 910,000 and the leucocytes 4,992 per c.mm. Both spleen and liver were enlarged. The aldehyde and urea-stibamine tests were both negative. Malarial parasites (*Plasmodium falciparum*) were found in the blood. She was treated

with atebirin after which the fever was checked, but there was no improvement in her condition. Her disease was diagnosed as Bengal splenomegaly. As it was an inoperable case, it was proposed to submit the spleen to deep x-ray exposures once a week. Twenty cubic centimetres of whole blood were given intramuscularly twice a week in order to stimulate the hæmopoietic organs depressed by deep x-ray exposures. She was then given 43 injections of muscle extract altogether. She improved slowly, but steadily. At the time of her discharge on 24th June she was completely free from ascites and her red blood cell count was 3,000,000 per c.mm.

Case 16.—Hindu male, aged 20 years, was admitted on 23rd March with a huge spleen, ascites, frequent attacks of fever, and anæmia. The patient was of stunted growth and looked like a boy of thirteen. There was no growth of hair on the face, arm-pits, or pubes. A spleen-puncture smear showed no leishmania. The aldehyde and urea-stibamine tests were negative. No malarial parasites were found on repeated examinations. The case was diagnosed as Bengal splenomegaly with secondary portal cirrhosis and ascites. The number of erythrocytes at the time of admission was 900,000 per c.mm., and the leucocytes were 8,000 per c.mm. The patient got an attack of bronchitis while in the hospital, and on 12th March began to sink into a collapsed condition. Although the patient recovered after getting transfusion of blood, he went down-hill day by day. A course of muscle extract was commenced on 2nd April. The temperature, which was fluctuating all along between 98° to 101°F., gradually touched the normal level and the patient began to improve in weight. The red blood cells increased to 1,900,000 per c.mm.

As this was not a suitable case for splenectomy, deep x-ray therapy of the spleen was started on 14th April with the idea of damaging the mononuclear phagocytes responsible for destroying the red blood cells in the spleen in this disease. The difficulty was that each exposure of x-rays diminished the number of erythrocytes. The red blood cells counted 1,910,000 before the exposure, but went down to 1,700,000 after the exposure. It was therefore decided to give intramuscular injections of 20 c.mm. of whole blood after each exposure. He had 9 exposures of deep x-rays and ten injections of whole blood alternately every week till 28th June. The number of erythrocytes increased to 2,960,000 per c.mm. Ascites disappeared completely. The courses of muscle extract were, however, continued and there was no further manifestation of cirrhosis of the liver in the shape of ascites. The patient gradually gained in weight and was greatly improved in general health. Three further deep x-ray exposures were given alternately with injections of whole blood and, when the patient was discharged on 22nd July, the number of red blood cells was 3,130,000 per c.mm.

Myoclonus

Muscle extract was further given trial to relieve myoclonic twitchings in a case of encephalitis lethargica with progressive bulbar paralysis.

Case 17.—Jew male, aged 53 years, was admitted on 17th September, 1931, to the Ezra hospital with the following complaints:

- (a) aphasia in articulation,
- (b) excessive salivation and difficulty of swallowing food,
- (c) weakness of muscles of the whole body, and
- (d) myoclonic twitchings all over the body.

The patient gave a history of fever a year ago, since when the above complaints gradually commenced and went on increasing. Physical examination showed marked atrophy of the tongue with furrows and fissures, and exaggeration of all deep reflexes. There were progressive paresis of the muscles of the palate and regurgitation of food through the nose. There was increased difficulty of deglutition. The Wassermann

reactions of both blood serum and cerebrospinal fluid were negative.

Treatment with calcium and parathyroid, milk injections, systematic attempts at re-educating his articulation, and iodides failed to improve his condition.

The treatment with injections of muscle extract was begun from 16th January, 1932. It was given intramuscularly in 0.5 c.cm. doses daily except Sundays. Ten injections were given. The myoclonic twitchings diminished remarkably after three or four injections. Salivation was stopped for some time. There was still a good deal of difficulty in deglutition and food still regurgitated through the nose when the patient left the hospital on 5th April.

The quick disappearance of myoclonic twitchings suggests that the action was due to removal of the ischaemic condition of the nerves, probably caused by some spasm of the vasa nervorum.

A SEROLOGICAL PROOF OF ETHNOLOGICAL IDENTITY OF THE HINDUS AND THE MOHAMMEDANS OF ASSAM

By P. N. MITRA, M.B., D.T.M.

Teacher of Pathology, Berry White Medical School, Dibrugarh

[With Comments by H. P. CHAUDHURI, M.B., D.P.H. (Lond.), D.T.M. & H. (Lond.), F.R.S.S. (Lond.), D.O.M.S. (Lond.), Honorary Research Worker, All India Institute of Hygiene and Public Health, Calcutta]

RECENTLY I had an opportunity of testing the blood groups of 2,000 persons. These included men of all castes and creeds, both sick

and healthy; among them were 1,565 Hindus and 355 Mohammedans. The table below shows their distribution according to their blood groups.

It will be seen that there is some difference among the percentages of the various groups, and the question arises whether the difference is of any significance.

Pearson (1911) shows that if we let the population from which the two samples, if undifferentiated, are supposed to be drawn be given by the class frequencies

$$m_1, m_2, m_3, m_4, \dots, m_p, m_q, \dots, m_s.$$

the total population being M , and let the samples be given by the frequencies in the

First sample	f_1	f_2	f_3	\dots	f_p	f_q	\dots	f_s	Total. N
Second sample	f'_1	f'_2	f'_3	\dots	f'_p	f'_q	\dots	f'_s	N'

same classes: where the total N and N' differ widely or little, and then form a quantity

$$\chi^2 = S_1 \left\{ \frac{N N' \left(\frac{f_p}{N} - \frac{f'_p}{N'} \right)^2}{f_p + f'_p} \right\}$$

where S_1 denotes summation of like quantities from 1 to s , that then the required probability that the two samples are undifferentiated, i.e., did come as random samples from the same population, may be found by looking out the value of P corresponding to the ascertained χ^2 and n' (the number of classes) from the tables given on pages 26 to 29 of Pearson's 'Tables for Statisticians and Biometricians'.

	GROUP A		GROUP B		GROUP AB		GROUP O		TOTAL
	Number	Per cent	Number	Per cent	Number	Per cent	Number	Per cent	
Hindus ..	390	24.93	498	32.73	145	9.26	532	33.98	1,565
Mohammedans ..	84	23.66	126	35.49	32	9.01	113	31.83	355

TABLE

		Group A	Group B	Group AB	Group O		TOTAL
Hindus ..	(i)	390	498	145	532	f	1,565
Mohammedans ..	(ii)	84	126	32	113	f'	355
(i) + (ii) ..	(iii)	474	624	177	645	$f + f'$	1,920
(i)/1565 ..	(iv)	0.2492	0.3182	0.0926	0.3399	f/N	..
(ii)/355 ..	(v)	0.2366	0.3549	0.0901	0.3183	f'/N'	..
(iv) - (v) ..	(vi)	+0.0126	-0.0367	+0.0025	+0.0216	$f/N - f'/N'$..
Square of (vi) ..	(vii)	0.00015876	0.00134689	0.00000625	0.00046656	$(f/N - f'/N')^2$..
(vii) ÷ (iii) ..	(viii)	0.00000033	0.00000018	0.00000003	0.00000072	$(f/N - f'/N')^2$..
		$= N \times N' \times 0.00000121 = 1,565 \times 355 \times 0.00000126 \approx 0.7060245$					0.00000126
		$= \text{say } 0.7$					

If $\chi^2 \approx 0.7$ and $n' = 4$, then $P \approx 0.801253 = \text{say } 0.8$.

That is to say there are 80 chances to a hundred in favour of the samples being random samples from the same population.

Conclusion.—There are 80 chances to a hundred in favour of the samples being random samples from the same population.

[**Note.**—The writer of this paper appeared to us to have shown originality and ingenuity in his approach of this subject, and, as we did not ourselves feel competent to judge the value of his contribution, either regarding the accuracy of his calculations or the justifiability of his conclusions, we sent his paper for criticism to a senior census officer. He pointed out that there was no reason to suppose that the blood samples from any other group of human beings would not give the same results. He further pointed out the dangers of drawing conclusions from such data, and quoted the example of a scientist who claimed to be able to diagnose pregnancy by some serological test and unfortunately diagnosed it in a sample of blood from a man.

We subsequently referred the paper for further opinion to Dr. H. P. Chaudhuri, Honorary Research Worker, All India Institute of Hygiene, Calcutta, who commented as follows:—

‘Hirschfeld (1919) was the first to suggest that from a study of blood groups it is possible to distinguish the different races of man. He examined the blood of soldiers of different nationalities during the great war; he evolved what is called “the bio-chemical race index” and showed that this was different in different races. Later, Ottenberg (1925) reviewed the work of several authors on this subject and came to the conclusion that with the aid of blood grouping the peoples of the world could be divided into six large groups. More recently, Malone and Lahiri (1929) tried to apply this method to smaller groups in India, such as the Turko-Iranian, Indo-Aryan, Dravidian and others, but found that “the bio-chemical race index” was an inadequate measure as it did not help to bring out clearly the difference or similarity between the different groups of men studied.

Now Dr. Mitra has gone a step further and attempted to establish the identity of Hindus and Mohammedans from a study of their blood groups. He has shown that there is 80 to 90 per cent agreement in the percentage distribution in the different blood groups between Hindus and Mohammedans. The mere fact of this similarity in attributes (that is, blood groups) implies nothing regarding their ethnological identity. In order to establish such an identity it is necessary to obtain information regarding the blood groups of non-Hindus other than Mohammedans, and in the absence of such information it is quite justifiable to contend that 80 to 90 per cent of non-Hindus other than Mohammedans may also show similar blood grouping. Therefore, unless Dr. Mitra produces evidence as to what percentage of non-Hindus, other than Mohammedans, are allied to or different from Moham-

medans, as regards blood groups, his work cannot be considered an important contribution to our knowledge of ethnological relationship of races. Biological tests are indeed of value in the study of racial differentiation, provided we confine ourselves to very broad groups, but, before we can accept results of these tests as evidence in support of racial identity of smaller and more closely-related groups, it is necessary to furnish figures that are above every chance of fallacy. Dr. Mitra has taken great pains in that he has studied over 2,000 bloods, but this does not mean that inadequate evidence and fallacious conclusions are justifiable or admissible.

To support his conclusions Dr. Mitra has sought the aid of a well-known statistical formula called “the chi-square (χ^2) test”. This formula owes its origin to Karl Pearson and is applicable to problems of the kind indicated in the following words by Raymond Pearl (1930): “given two frequency distributions of phenomena, (1) what is the probability on the one hand that the two can be regarded as random samples from the same population whose characteristics are known from the samples only or (2) what is the probability that the one distribution is really different from the other to a greater degree than could reasonably be supposed to have arisen by the operation of chance alone”. Applying this test to Dr. Mitra’s figures one can merely conclude that as regards blood groups Hindus and Mohammedans in Assam are almost identical. It by no means establishes their identity; at most, one may say that it gives an indication that possibly there is some ethnological relationship between the two communities’.—

A Mirror of Hospital Practice

FILARIAL WORMS UNDER THE HUMAN CONJUNCTIVA

By S. SUNDAR RAO, L.M.P.

Calcutta School of Tropical Medicine

THE first record of a worm in the eye appears to be by Mongin in 1770. *Loa loa* (Guyot, 1778), a human filaria which commonly appears in the eye, is confined chiefly to the west coast of Africa. The adult parasites are smaller than *Wuchereria bancrofti*, have a

PLATE VIII

Showing two worms under the left conjunctiva, one on
either side of the cornea.

truncated cuticle, live in the superficial connective tissue and very frequently appear under the conjunctiva. The embryos, discovered by Manson in 1891, live in the blood stream and exhibit a diurnal periodicity. Manson suggested that a day-biting mangrove fly might be the carrier of this worm and Leiper showed partial development of the embryo in *Chrysops dimidiata* and in *C. silacea*. This was later confirmed by Kleine and by Connal.

The presence of filarial worms in the human eye is a rare occurrence in this country. As far as the author is aware there are only two records of such cases. Charles (1920) reported an adult male, aged 45, resident of Sialkot district, who had a fairly large swelling on the inner and lower side of right eye beneath the ocular conjunctiva. On opening the swelling under local anaesthesia a loop of living worm came out. The whole worm was removed and was later identified by Sewell as probably *Filaria conjunctivae addarioi*, 1885.

The next case was reported by Das Gupta (1921) from Ramporehaut. In a Mohammedan male, aged 25, was found a cystic tumour near the outer canthus. On opening the cyst, 'two fine living worms measuring $1\frac{1}{2}$ inches coiled up together, one slightly larger than the other' were found. They have not been identified.

Recently an interesting case of this type came under my observation. The following are the brief notes on the patient :

Miss M. J., Jewess, aged 16, living in Rawdon Street, Calcutta, since childhood; suffering from elephantiasis of the left leg for the past 4 years. Several members in the family are infected with *Wuchereria bancrofti*. She came to the filariasis clinic on 2nd December, 1932, for treatment of the swelling of the left foot and ankle and she complained of slight dimness of vision in the left eye which had been gradually growing worse for the last seven months on the least eye-strain. On examination, two worms, one on either side of the left cornea, were seen coiled up just under the conjunctiva (see plate VIII). The worms were so prominent that they were visible from a distance. The patient was admitted into the Carmichael Hospital for Tropical Diseases on the same day. One worm was seized with forceps and held during removal of the portion of conjunctiva containing it, by Lieutenant-Colonel Kirwan, I.M.S. As the first worm was being removed, the one lying near the inner canthus disappeared temporarily and reappeared in the original site after 3 days, when it was excised. Neither of the worms could be found although the whole of the portions of conjunctiva removed were sectioned, mounted serially and examined. The patient has been under observation for more than three months since the above operation and the worms have not appeared again in the eye.

Blood examined on several different occasions showed no microfilariae. Total white blood cell count:—8,600 per cubic millimetre. Differential count:—Polymorphs—72 per cent, lymphocytes—17 per cent, mononuclears—5 per cent, and eosinophiles—6 per cent. Stool examination showed scanty *E. histolytica* cysts and *Trichuris* ova.

A CASE OF TABES DORSALIS IN AN INDIAN

By P. N. WAHI, M.B., B.S.

Senior House Physician, King George's Hospital
and

G. T. BURKE, M.D., M.R.C.P.

LIEUTENANT-COLONEL, I.M.S.

Physician, and Professor of Medicine, King George's Medical College, Lucknow

TABES DORSALIS is sufficiently rare amongst Indians to be worth recording, and the present case presents many typical symptoms.

K. L. A., male, Indian Christian, aged 45, who had never been out of India, was admitted to the ophthalmic ward for drooping of the right upper lid, and was soon transferred to the medical wards.

History.—For two years he had suffered from shooting pains in the lower extremities—described by him as 'electric shocks'—the attacks lasting for fifteen to twenty minutes, and recurring at indefinite intervals of fifteen days to four months, and being experienced mainly in the calves. Coincidentally he had felt a sensation as of a tight rope round his waist at the level of the tenth and eleventh dorsal vertebrae.

For a year and a half he had experienced difficulty in balancing himself, noticed most when washing himself in the morning, for on closing his eyes he would fall forward into the basin.

About six months previously he noticed dimness of vision in the left eye, and at the same time found the right eye deviated inwards and experienced diplopia. He was treated for these troubles in the ophthalmic outpatient department by electric massage and anti-syphilitic measures, though the Wassermann reaction of his blood was negative, both before and after a provocative dose of neosalvarsan. His squint became much better after three months. One and a half months before admission he noticed partial drooping of the right upper lid.

Condition on admission.—A well-built man, who walks with difficulty with a staggering gait, and at once falls on closing his eyes. He complains of frequent pains in his lower limbs, and of the sensation of a continuously present tight band round his waist.

Cranial nerves.—The right eye is slightly deviated outwards and the right upper lid droops slightly; the internal movement of the right eye and external movement of the left eye are defective; the pupils are unequal, the right being the larger; the right pupil does not react to light but reacts sluggishly to accommodation; the cilio-spinal pupil reflex, while present in both, is very sluggish in the right eye; the consensual light reflex is present in the left eye only; Wernick's hemianopic pupil reflex is not present; vision is 6/6 in both eyes; fundus examination shows no abnormality.

Outside the eyes the only cranial nerve abnormality is a weakness of the right facial muscles.

Upper extremities show no change, motor or sensory.

Lower extremities show defective co-ordination, but normal motor power. Sensations of heat, cold, touch, and pinprick are normal, but muscle sense and vibration sense are absent in legs and feet. The deep reflexes are completely absent, and the plantar reflex gives no response.

Trunk.—No area of anaesthesia could be found, band or other.

Blood.—Wassermann negative.

Cerebro-spinal fluid.—Wassermann strongly positive. Cell count 25 per cm.

The diagnosis cannot be doubted. Treatment by intra-thecal injections of salvarsanized serum by Swift Ellis' technique were commenced. The patient was given an injection of 0.6 gramme neosalvarsan. Twenty minutes after this about 30 cubic centimetres of blood was withdrawn, to yield some 15 cubic centimetres of

serum. The blood was kept overnight in an ice chest, and next day was centrifugalized and the clear serum pipetted off and made up to 30 cubic centimetres by the addition of normal saline. The salt-serum mixture was kept for half an hour in a thermostat.

Lumbar puncture was performed in the lateral position, and 25 cubic centimetres of cerebro-spinal fluid withdrawn; 30 cubic centimetres of the salt-serum mixture was then introduced through the needle, so as to diffuse under pressure. Two such injections were given, with about two weeks interval; after each one, at about four hours interval, the patient experienced lightning pains of the severest type, with increase of the girdle sensation, so severe as to demand morphia in full doses. The pains lasted about six days. The patient removed himself from hospital without more treatment.

A CASE OF FIBRO-LIPOMATOSIS ASSOCIATED WITH FEVER

By G. T. BURKE, M.D., M.R.C.P.

LEUTENANT-COLONEL, I.M.S.

Physician

and

P. N. WAHI, M.B., B.S.

Senior House Physician, King George's Hospital,
Lucknow

R. D. P., male, aged 24 years, was transferred to this hospital at the end of November 1932, being under artificial pneumothorax treatment for pulmonary tuberculosis, with the history of recurring attacks of high fever not apparently attributable to the tuberculous infection.

He was a lad in fairly good general condition, with one lung collapsed and the other clinically and radiologically healthy, and no signs of disease elsewhere. He ran an intermittent temperature from 30th November to 12th December of 101°F. to 104°F. each evening, the morning record being normal. The fever was neither preceded by rigor nor followed by sweating. From the beginning the patient insisted that the fever was connected with the appearance of small nodular swellings under the skin, and pointed out a number of what appeared to be fibro-lipomata, but at first not much importance was attached to his statement.

On the 8th January the temperature again rose to 101°F., and the patient called attention to a small nodular swelling on the left forearm which, he said, had just appeared, and this swelling was carefully watched. It started as a painful red indurated area with pain on moving the limb; in a few days in this area a firm painless nodular mass was felt, about the size of a small pea; this slowly increased in size for three or four days and then remained stationary. Meanwhile similar nodules had appeared elsewhere. The swellings ceased to appear in about a week and the temperature settled down on the 16th, having ranged daily from 101°F. to 104°F.

On the 30th January the patient again had a short attack of fever of milder intensity, accompanied by the appearance of more swellings, the first being on the posterior aspect of the left leg.

Altogether, during approximately two years, about eighty swellings had appeared in different parts of the body, and could be felt as small firm subcutaneous masses, movable and painless, and resembling those seen in von Recklinghausen's disease. The patient said he could foretell each attack of fever by the appearance of these swellings.

During this period the treatment by artificial pneumothorax was maintained with clinical success.

The following pathological findings were made:—

The blood, urine and feces were normal, and no parasites were found. Histological examination of one

of the swellings showed the structure to be a fibro-lipoma.

Though different forms of fibro-lipomatosis have been described including that of von Recklinghausen, and some are painful, we cannot find any record of the appearance of such growths accompanied by attacks of fever. Clinically they resembled molluscum fibrosum, though none of them were larger than an almond. The nodules in *tuberculosis dolorosa* are painful, but are usually neuro-fibromata: these nodules were not painful after they had ceased growing, and the histological examination revealed no nervous tissue.

The patient left hospital in mid-February for a sanatorium.

A CASE OF CUTANEOUS PLAGUE

By C. F. DE ROZARIO, L.M.S.

Assistant Surgeon In-Charge, Government Isolation
Hospital, Bangalore

A HINDU, aged 22 years, a student, was admitted to hospital with a history of high fever for the past four days and an acute spreading ulcer on the left side of chest wall which started as a pustule two days after the commencement of the fever. There was no history of proximity to plague infection.

A hard mass about the size of an almond was situated about 4 inches above the ulcer. In spite of energetic local and general treatment his condition became worse and three days after admission two more ulcers appeared near the first one.

The margins of the ulcers progressively extended giving the appearance of large areas of gangrenous integument with a tendency to surrounding bleb formation suggestive of the toxins of *Bacillus oedematis*. So anti-gas gangrene serum 4,000 units was injected. By this time the patient was very seriously ill.

Smears taken on the fifth day were reported by the pathological department to contain *B. pestis* and this was subsequently confirmed by animal experiments.

A week after admission the patient was delirious with subsultus tendinum—condition very low—ulceration greatly extended—covering an area of about one square foot—exuding foetid discharge, enlargement and tender masses of glands in the cervical, femoral and epitrochlear regions on both sides.

On the following day the left eye became acutely inflamed; this ended in complete destruction of the cornea from ulceration causing total loss of vision.

After a protracted convalescence in which the femoral gland buboes had to be opened and drained the patient was finally discharged from hospital cured, two months after admission.

A few points of interest about this case are:—

(1) An exact description of the ulcers appears in *Manson's Tropical Diseases*, ninth edition.

(2) On admission, although the patient gave a history of four days' illness, he did not look at all ill.

(3) Despite the presence of the ulcers on the chest wall there were no buboes or enlarged glands present on any part of the body until the twelfth day of disease.

(4) Keratitis which resulted in total loss of vision in the left eye is a rare complication.

Published by kind permission of Brevet-Colonel J. McPherson, I.M.S., Residency Surgeon, Bangalore.

JULY

TRAINING FOR MATERNITY AND INFANT WELFARE WORK

ONE of the most hopeful omens for India's future is the increasing interest that her sons and daughters are displaying in maternity and infant welfare work. Though pioneer workers organized centres in a few of the larger towns and in certain model village settlements some years ago, it is only during the last five years or so that the interest in this form of social service has become widespread and reached the rural areas. It is unfortunate that this sign of the quickening of the social conscience in India should have been so timed that its infancy will have to be passed in a period of great financial depression. The survival of this movement will depend on the determination of its supporters and the next few years will show whether it was a passing phase of nationalistic enthusiasm or a genuine appreciation by the educated classes of their duty to the masses.

Hitherto the organization of this work has been a matter of personal local effort and, though in certain cases governments and municipalities have given grants in aid, most of the money expended has had to come from the pockets of the active supporters of the movement or from those of their friends. This is the history of welfare movements in other countries and, although when the value of the movement has been established and when money is less scarce the whole organization may be financed from public funds, it is a state of affairs in which, in the present circumstances, there is nothing intrinsically wrong; a social conscience which urges a man to sit down and write to the papers demanding that the government shall do something about it, but does not stimulate him to make some personal effort is barely worthy of the name. In India the government spends a greater proportion of its total revenues on medical relief, by the provision of free hospital and dispensary treatment, and on public health measures, than is the case in many other countries. The contention of the sanitarian is that by public health measures rather than by the temporary amelioration of the symptoms of the individual—which is often all that hospital and dispensary treatment can hope to achieve—the most lasting benefit to the community is likely to be effected, and that therefore this should be the first consideration of the government. At the present time this is not the case; a much greater sum is expended on

the provision of hospitals and dispensaries than on preventive measures. This is a point of view with which we are in entire agreement, but it is not the popular one; the demand is for more and more hospitals and dispensaries. In these circumstances a wholesale deflexion of public funds from the medical relief budgets to the public health (or prevention) budgets would be very unpopular, and is therefore out of the question, *until the people have been taught by demonstration to appreciate the value of preventive measures.* We will return to this point later; meanwhile we will refer to some of the requirements, and some of the shortcomings, of the present-day welfare organizations in this country.

Voluntary workers have little sympathy with the collection of statistics; they consider them as a form of official red tape which they in their 'voluntary' capacity are lucky to be able to avoid. On the other hand the trained public health worker knows that schemes of work follow, not precede, the proof of the necessity for them, and that in the absence of reliable statistics it is impossible to determine what is the most urgent need and what form of public health measure will bring the greatest advantage to the largest number of people.

Statistics for the incidence in and death rate from certain epidemic diseases throughout India are available and, although it is fully realized that these are not correct in detail, it is generally accepted—and we think quite rightly—that they give a very fair indication of the relative incidence of these diseases year by year and district by district. However, maternal mortality statistics are notoriously incorrect everywhere. Bombay, which has a special municipal order relating to maternal deaths and is therefore probably above the average as regards accuracy in this respect, will serve as an example.

The following figures are taken from the 1931 report of the Medical Officer of Health for Bombay:—

Number of births	Number of maternal deaths	Maternal mortality
27,204	198	7.2

The two largest maternity hospitals in Bombay together report 171 maternal deaths *plus* 9 deaths due to general diseases associated with pregnancy in a total of 6,767 births, a maternal mortality rate of 25 per mille. This leaves a balance of 27 deaths amongst 20,427 births in other hospitals and in the general population; this is of course ridiculous. Further discrepancies will be found if we look into the causes of death. These are given below in tabular form. The percentages have been calculated and the corresponding figures for England and Wales given for comparison.

Cause of death	BOMBAY				ENGLAND AND WALES
	M. O. H's. REPORT		HOSPITALS		
	Number	Percentage	Number	Percentage	Percentages
Anæmia of pregnancy	17	8.6	43	23.9	..
Sepsis	93	47.0	36	20.0	37.1
Eclampsia and other toxæmias	39	19.7	14	7.8	17.6
Operative shock	11	5.6	8	4.4	9.9
Hæmorrhage	21	10.6	16	8.9	14.3
Other diseases	17	8.6	63	35.0	20.8
Other accidents of pregnancy					
TOTALS ..	198	..	180

That is to say 17 persons are reported as having died of anæmia of pregnancy in the whole of Bombay and yet 43 died of this condition in two of the hospitals in the city; further comment is unnecessary. Incidentally this table emphasizes the importance of anæmia as a cause of death in the Bombay hospitals, as compared with sepsis and would appear to indicate the importance of antenatal care rather than improvement in midwifery practice as a means of reducing the death rate, but it is obvious that when registration and returns are so palpably inaccurate they cannot be used as a guide to action.

Bombay has been taken as an example because it has special arrangements regarding maternal death registration and yet the figures are demonstrably incorrect; the same unreliable information (or no information whatsoever) is all that is available in any part of India on a subject of such vital importance to the nation as the health of the mother and her baby. Information on the subject of infantile mortality is equally defective and misleading. The figures available give the infantile mortality in various places in India as varying between 137.8 (Bihar and Orissa) and 329 (Lucknow); the rate in Calcutta, for example, is 278. A health visitor kept a record of all the births and deaths occurring in the lines of a jute mill for a period of five months; during this period there were 63 births and 19 of the infants died, of which 16 died in the first month; making allowances for the fact that only half the deaths in the last month would be recorded, these figures indicate a mortality rate of 282 per thousand births, in the first month of life. The causes of death included tetanus neonatorum in five instances, heat stroke in three, and other equally avoidable conditions. The cause of this appalling mortality is not only the lack of suitable medical and nursing provision, but is also the result of social custom and prejudice, and demonstrates the necessity of carrying the teaching of the fundamental principles of

cleanliness and fresh air into the homes of the people, who are too fatalistic, too careless of human life and too indifferent to suffering to seek enlightenment for themselves.

Epidemic diseases, on account of the dramatic severity of their onset and the number of deaths they cause in a short time, arouse public attention and lead to a demand for relief and even preventive measures; but epidemic diseases come and go; pregnancy and labour we have with us always. There are in India over eight and a half million childbirths yearly, but the incident is so familiar in our daily lives that we give little thought to its consequences, yet the sum total of unnecessary deaths and disablements that result over a period of ten years must rival the ravages of any single disease, with the possible exception of malaria, over the same period. Public health authorities are but servants of the public and, though they play a very important part in educating the public, meanwhile they are to a certain extent compelled to direct their activities where public opinion demands them. If the number of maternal and infantile deaths in which an avoidable factor plays the major part could be estimated, the public conscience would be stirred. Hitherto the organizers of the welfare movement have not made the most use of their opportunities to obtain accurate figures on these subjects; the reason for this is that they are in most cases untrained and have not the knowledge or the appreciation of the value of vital statistics so essential for all welfare workers.

Many welfare schemes fail to make the most of their opportunities by attempting too much. The cause of this defect lies in the preponderating humanitarian outlook of the voluntary worker who wants to bring relief—and immediate relief—to the largest number of persons possible. We can sympathize with this point of view although it usually leads to the misdirection of effort and little permanent benefit. Welfare schemes should have as their objective the raising of the standard of physical and

mental health of the community; to confine their activities to restoring and maintaining the health of a few scattered individuals by the giving of medicine, milk and baths is to fail to keep this objective in view. The weaning of the people from their old-established and insanitary customs and practices alone will raise the standard of public health, and an intensive educational campaign, through the maternity and child-welfare organizations and health education in schools, with this end in view is the duty of the health department of every province. Mere reiteration of health precepts will, however, be insufficient to convince the people and practical demonstrations will form an essential part of such a scheme. The present lack of trained personnel, not to mention financial considerations, make comprehensive schemes out of the question, and the choice lies between indifferent work over a wide area and intensive work in a limited one; the latter is obviously preferable from all points of view because it provides more striking results for the education of the people, as well as a better opportunity for obtaining a proper estimation of the value received for the money expended.

The provision of trained personnel for directing welfare schemes is beyond the powers of the voluntary organizations who quite rightly look to governments and local authorities for help in this direction. Certain progressive municipalities are initiating schemes and with the return of prosperity others are bound to follow suit. Then, the real tragedy of the present position in India, the lack of properly trained medical personnel will become more and more apparent. Many schemes, excellent in conception, fail in execution because the staffs appointed to administer and carry out the work lack the preventive outlook. Prevention is invading the medical curriculum, so long the stronghold of curative medicine, but the whole bias in practical training is still towards the recognition, the study and the cure of established disease, and it is futile to expect the doctor, taught on these lines, to give up immediately the only methods he (or she) knows, in favour of the study of health, and of its promotion by education and advice in environmental and personal hygiene. The medical officer of health is not called upon to organize the health services of a province or city without being specially trained for the work, and it is absurd to expect a doctor who has no idea how to survey an area with regard to its public health needs, who knows nothing of the cost of, or how to train, the necessary staff, and who knows nothing of vital statistics, of epidemiology, or of public health law, to organize and administer a maternity and child-welfare scheme, when perhaps his only idea of welfare work is vaguely that its object is to reduce the infantile and maternal death rates, and when he is incapable of visualizing the distant goal of racial betterment through the teaching of

hygiene, eugenics and population control. It is futile to expect that he, or she, will even make a good executive officer, supervise the work of the health visitor and midwife, train the dai, or advise with authority on breast and artificial feeding and on the upbringing of difficult children, when the opportunity for the study of child physiology, children's diseases and child psychology are as limited as they are to-day in most Indian universities.

To meet the needs of the provinces and larger towns for administrative and executive officers for maternity and infant welfare, a diploma course in the subject is, we understand, being arranged at the All-India Institute of Hygiene and Public Health in Calcutta. The syllabus will probably be similar to that for the diploma of public health, the chief difference being the omission of subjects, such as sanitary engineering and public health physics, and the provision of more opportunity for lectures and practical work in advanced midwifery, infant care and management, child psychology, school hygiene, the organization of child-welfare schemes, and similar subjects.

A section for maternity and child-welfare and school hygiene was one of the six sections included in the original scheme for the All-India Institute of Hygiene and Public Health, but unfortunately it is not one of the four sections that the Government of India has decided that in the present circumstances they can afford to finance. However, so important do the managing body of the Women's Medical Service consider the provision of skilled services for the protection of child life and health amongst the various plans for national advancement, that they have deputed a member of the service to organize the department and to inaugurate a model welfare scheme where the practical training in connection with the diploma may be carried out. It is hoped that government sanction will be obtained for the opening of the course in October under her direction.

The outstanding need for the welfare of the mother and child in India to-day is a body of trained medical men and women to reorganize existing welfare schemes and to institute a programme of steady extension of this work throughout the whole country. The commencing of this course at the All-India Institute in Calcutta will provide the opportunity for meeting this need. We have little doubt that there will be a sufficient number of candidates for this course, and the responsibility for the full attainment of the object of its institution will now fall on the various provincial governments, municipalities and other public bodies to provide training scholarships and thereafter suitable posts and opportunities for the successful candidates to put their knowledge into practice; if they do so, the maternity and infant welfare movement in India will have been placed on a sound foundation.

Medical News

FORLANINI

At the two conferences of the International Union against Tuberculosis held in Rome in 1928 and in Oslo in 1930, it was decided to open in all countries a subscription on behalf of a monument to the memory of Forlanini.

The inventor of the artificial pneumothorax not only endowed medicine with the first really active and efficient method for the cure of tuberculosis, but his discovery paved the way to all the collapse-therapy methods with which medicine is to-day fully armed to overcome this disease.

All patients and physicians in India will, we feel sure, be pleased to have this opportunity of showing their gratitude to this illustrious son of Italy. Even the most modest donation, as well as a larger contribution, will be welcome. This appeal has reached us through the Comité National de Défense contre la Tuberculose, which has undertaken to collect the French donations, and the Indian Red Cross Society which has undertaken to collect those from India and to forward them to the right quarter. In these times one cannot expect large donations, but the object is to make the memorial an international one and it would be a pity if India did not contribute her share. We therefore appeal to all physicians, and through them to their patients, particularly those who have received benefit from this form of treatment, to answer this urgent appeal for subscriptions to Forlanini's memorial.

UNITED PROVINCES MEDICAL COUNCIL

THE Registrar of the United Provinces Medical Council has forwarded to us the following extract from the minutes of the meeting of the United Provinces Medical Council held on 1st May, 1933:

The letter of Dr. T. N. Varma, regarding medical officers in Government service writing prescriptions on printed forms supplied by certain chemists and druggists, was read.

Resolved that this Council looks with strong disfavour on the practice of medical practitioners writing their prescriptions on forms supplied by chemists and druggists bearing their name and address, and advertisement.

Further resolved that this decision of the Medical Council should be sent for publication to daily papers, the vernacular papers and the medical journals.

INDIAN MEDICAL BIRTHDAY HONOURS, 1933

THE following are the names of medical men and others associated with medical institutions in the Indian Honours List of date 3rd June, 1933. We would offer them our congratulations:

Knighthood

Colonel R. McCarrison, Indian Medical Service, an officer of the Indian Research Fund Association.

Dr. Kedar Nath Das, Principal, Carmichael Medical College, Calcutta.

C.I.E.

Brevet-Colonel James Macpherson, Residency Surgeon, Bangalore.

Lieutenant-Colonel W. L. Harnett, Professor of Surgery, Medical College, Calcutta.

Dr. J. N. Duggan, Professor, Grant Medical College, Bombay.

O.B.E.

Dr. E. D. Shroff, Health Officer, Karachi Municipality.
Captain M. R. Sinclair, on special duty with the Political Officer, Sikkim.

Kaiser-i-Hind (Gold Medal)

Mrs. L. M. Hope, Medical Practitioner, Bengal.
Lieutenant-Colonel S. G. S. Haughton, Indian Military Hospital, Quetta.

Kaiser-i-Hind (Silver Medal)

Miss Mary Clare Albuquerque, Medical Officer, Maternity Hospital, Bangalore.

Miss Janet Alexander, Lady Doctor, Mission Hospital, Montgomery, Punjab.

Miss Sarah Love McRobbi, Superintendent, Memorial Hospital, Fatehgarh, U. P.

Miss S. J. Rankine, Assistant Medical Officer, St. Margaret's Hospital, Poona.

Khan Bahadur

Dr. Abdul Qaiyum, Provincial Medical Service, Officiating Civil Surgeon, Manbhum, Purulia, Bihar and Orissa.

Rao Bahadur

Dr. Rajangam Siva Subramania Aiyar, Civil Surgeon, Insein and Hanthawaddy Districts, Burma.

Dr. K. R. Thampi, Inspecting Medical Officer (Retd.), Travancore.

Khan Sahib

Dr. Kahir Hossain, Bengal Medical Service, Senior Teacher, Medical School, Jalpaiguri, Bengal.

Dr. Haji Bashiruddin Ahmed, Sub-Assistant Surgeon, at present posted as Medical Officer in charge of Bongaon Sub-division and Dispensary, Jessore, Bengal.

Dr. Abdul Majid Khan, Provincial Subordinate Medical Service, Medical Officer in charge, Baghpatt Dispensary, Meerut District, U. P.

Rai Sahib

Dr. Adhar Nath Sanyal, Medical Officer of Health, Farrukhabad, U. P.

Dr. Suraj Mal Sarien, Chief Medical Officer, Dholpur State, Rajputana.

Rao Sahib

Dr. Y. G. Vasudeva Ayyar Avargal, District Health Officer, Salem, Madras Presidency.

Dr. S. Kumaraswami Pillai, Avargal, Civil Surgeon, Madras Presidency.

Dr. Rajaram Dattopant Parulkar, Medical Officer of Health, Bijapur Municipality, Bijapur.

Dr. Jhalashankar Samapdas Shad, Chief Medical Officer, Wankanner State.

FIFTY YEARS AGO

(From the *Indian Medical Gazette*, July 1883)
Précis of Operations performed in the Wards of the first Surgeon, Medical College Hospital, Calcutta, during the year 1882.

Lithotomy.—Mahomedan male, æt. 60; symptoms of 3 years' duration, urine alkaline, traces of albumen. Left lateral lithotomy performed; bilateral section of prostate made, stone weighed 1 oz. 6½ drs.; made a good recovery in 37 days.

* * * * *

Lithotrity.—Mahomedan male, æt. 36; symptoms of 2 or 3 years' duration. Stone crushed on three occasions, on 3rd, 10th, and 14th of March; suffered from a smart attack of fever after the first operation; very little vesical irritation. Remained 44 days in hospital.

* * * * *

Plastic operation for restoration of lip.—Hindu male, æt. 30. Had suffered from a carbuncular boil of lower lip 4 years ago, 6 teeth and a corresponding length of gum exposed. A flap was taken from the chin and transplanted upwards. This served to supply the deficiency and conceal the teeth and gums. Remained 22 days in hospital.

Change in the size of the red corpuscles.—Mensuration of the corpuscles was effected by drawing with the

aid of a camera lucida ten corpuscles, and then calculating their mean diameter.

The size of the red corpuscles in health is a tolerably constant quantity—the diameter usually given in the textbooks ranging from $1/3,500$ th to $1/3,200$ th of an inch, that is from 7.3μ to 7.9μ . Cornil and Ranvier give the mean diameter as 7μ

* * * * *

That the red corpuscles do not always contain a constant quantity of hæmoglobin was conclusively demonstrated by Johann Duncan in 1867; and has since been amply confirmed by Malassez, Hayem and many others.

The several clinical methods devised for determining as accurately as possible the relative quantity of

hæmoglobin in the blood all agree in the principle of contrasting a solution of blood of known strength with certain standard colours or coloured substances corresponding to the tint of a solution of normal blood. Of the different instruments the simplest and readiest of application is Gowers's* modification of Malassez's original apparatus, where the standard of comparison is tinted glycerine-jelly made to represent the colour of 20 cubic millimetres of normal blood diluted 100 times—thus allowing of the amount of hæmoglobin, in the blood which is examined, being stated in terms of a percentage with reference to normal blood. Gowers's hæmoglobinometer was used for the present series of observations.

Current Topics

The Modern Conception of Nephritis

By T. IZOD BENNETT, M.D.

(Abstracted from the *Lancet*, 7th January, 1933, p. 8)

ALL those who have been engaged in the active practice of medicine during the last 20 or 30 years must agree that there has been an astonishing change in the precision with which a diagnosis can usually be established. However much one may reverence the experience and clinical instinct of the great physicians of the last century and the epoch immediately preceding the war, it would be foolish to pretend that they were capable of identifying and classifying disease in a manner in any way approaching what is possible to-day. If we reflect on what would happen during a teaching round in a medical ward before the war, we remember most brilliant teachers arriving at conclusions which were often accurate as regards the broad nature of the disease, and not infrequently genuinely precise when the post-mortem room revealed the ultimate details, but the contrast between this and a visit to the wards of a modern hospital is really very great. To-day you will go to such a ward and see, for example, a series of cases of this description—an ulcer on the lesser curvature of the duodenal cap, a case of pernicious anæmia, with the blood nearly restored to normal but with subacute combined degeneration of the cord, a case of pulmonary tuberculosis with the disease confined to the right apex, a case of sacro-iliac strain, a case of carcinoma of the fundus of the stomach, a case of tetany due to chronic steatorrhœa, a case of hypertensive cardiac failure with auricular fibrillation, a case of dysphagia due to achalasia of the cardia, a case of diverticulitis with recurrent pain and pyrexia. These are everyday cases, and the point which I wish to emphasize is that you will find precise diagnosis established in every one of them to-day, whereas 15 years ago this was not possible, at any rate as a rule.

I do not wish to imply that this is entirely due to laboratory methods and the help of x-ray examination; it is very largely due to these things, but actually precision is often reached to-day through the more exact knowledge which experience, gained by the help of these ancillary services, has given us.

KNOWLEDGE OF NEPHRITIS

When we come to nephritis it must at once be admitted that there are, in spite of the brilliant work of a host of investigators, enormous gaps in our knowledge which prevent us from achieving that precision which exists with regard to many other common diseases. Anyone accustomed to survey the world's literature dealing with nephritis is aware of considerable divergence of opinion, sometimes between country and country, and even more often between different authorities in the same country. At the same time, I would suggest to you that the last five years have

seen the emergence, in many different countries, of an important agreement concerning the major aspects of nephritis amongst a body of workers who have studied the subject deeply, sometimes in collaboration, sometimes independently. These workers, amongst whom I would include Fishberg, van Slyke, Epstein, and Addis in the United States, Achard in France, Volhard and Fahr in Germany, Snapper in Holland, and Gainsborough and others in this country, are steadily reaching close agreement as to the classification of nephritis, both as regards its clinical course, its ætiology, its morbid anatomy, and its biochemical manifestations, and although I think not one of them would suggest that anything approaching finality has been reached, they nevertheless represent an agreed conception concerning the general features of nephritis which is something quite new in the long history of medical inquiry into this subject.

I cannot put before you more than a somewhat fragmentary outline of the major points in this conception, but some of these will, I think, be of value in deciding when, and in what manner, a person with a history of nephritis, or with evidences pointing to nephritis, can be accepted by the examiner for life insurance.

RENAL FAILURE

The first conception to which I would draw attention is that of 'renal failure'. By this we mean a condition in which so great a proportion of the total kidney substance is temporarily or permanently out of action that the physiology of the body is deranged.

The normal kidney is made up of a vast number of individual units, each of which begins in a glomerulus; nature has provided far more of these units than are essential for life; it is a common observation that half the total kidney substance—i.e., one of the two kidneys—may be lost without permanent impairment to health, and we know that actually between two-thirds or three-fifths of the total kidney substance must be out of action before renal failure is established. A useful analogy may be drawn between renal failure and cardiac failure; each of these conditions may be temporary or permanent, and each of them may be compensated or decompensated. Just as toxæmia may produce acute cardiac failure from which the patient ultimately recovers, so an acute nephritis may produce a condition of renal failure which is not by any means necessarily permanent or fatal. As regards compensation, the analogy is less exact because long-standing compensated renal failure is a much rarer phenomenon than compensated cardiac failure, and is seldom compatible with prolonged good health.

The conception of compensation and decompensation in renal failure depends on recognizing that the main function of the kidney is the elimination of those superfluous chemical products which are found in the urine.

nitrogenous matter, particularly urea, being the most important. In order that the elimination of these bodies may be accomplished with a minimal loss of water the kidney has the power of concentrating many of them in such a way that normal urine exhibits an enormously greater concentration of urea than does the blood. The damaged kidney shows its failure first of all by a loss of this concentrating power; it still succeeds in eliminating the daily quota of urea and other substances, but can only do this by pouring them out together with considerable amounts of water. In consequence of this we have polyuria as the first sign of renal failure, and this polyuria is a compensatory process because the kidney is still fulfilling its major function of maintaining the blood chemistry practically constant. If renal failure persists the kidney becomes unable, even with the aid of increased water excretion, to rid the blood entirely of excess of urea. Uncompensated renal failure is then present and change in the blood chemistry can be demonstrated, this change being most often in the form of an increase in the urea and non-protein nitrogen. The following table represents the main findings in compensated and uncompensated renal failure:—

		RENAL FAILURE	
		Compensated	Uncompensated
Urine {	S. G. ..	Never above 1020	Seldom above 1015
	Urea ..	Below 2 per cent	Below 1.7 per cent.
Blood	Urea below 40 mg.	Urea 40-300 mg. N.P.N. 40-300 mg.
Symptoms	Polyuria	Polyuria. Gastro-intestinal symptoms.

It must next be emphasized that renal failure is a disturbance of function which may occur in any form of renal disease. It may occur during an acute nephritis or as the termination of a chronic nephritis, or it may occur in such conditions as damage to the kidneys from prostatic obstruction, polycystic disease, or tuberculosis of the whole urinary tract. It is a clinical state and not a disease in itself, and the prognosis, when it is present, depends on the disease causing it and the therapeutic possibilities which such disease may exhibit.

URÆMIA AND PSEUDO-URÆMIA

The understanding of the conception of renal failure is important because it is now considered that uræmia is explicable by the ancient conception of Bright—namely, that it is a chemical intoxication largely due to the accumulation of urea in the blood. For several generations this conception has been rejected because of the frequency of persons dying with obviously diseased kidneys but without any notable increase in the concentration of urea and non-protein nitrogen in the blood. Observers therefore sought for some toxic substance other than urea which might be the principal agent producing uræmia, and it was commonly believed that nitrogen retention, when present, was merely an index of disordered blood chemistry, and that the unknown toxin responsible for uræmia might be present in the absence of these other signs. To-day it is believed by the group of workers to whom I have referred that the term uræmia should be reserved solely for those cases in whom there is gross nitrogen retention. We recognize a condition of compensated renal failure in which there is a normal blood chemistry maintained by the mechanism of polyuria; we next recognize a condition of uncompensated renal failure with polyuria but with an increasing concentration of urea and other chemical substances in the blood; and, finally, we recognize a condition of true uræmia in which the blood-urea has become enormously elevated, giving figures

always above 150 mg. per 100 c.cm. and usually in excess of 200.

This condition of true uræmia is characterized by gastro-intestinal disturbance and deepening coma. Other manifestations, air-hunger, twitching, and so forth, often accompany it, but these are not essential; they are the results of varying secondary changes in the blood chemistry, such as lowering of the alkali reserve and hypocalcæmia. If I were asked for the most characteristic clinical sign of true uræmia I would say that it is the occurrence of a metallic or ammoniacal taste in the mouth due to the presence of large quantities of urea in the saliva, and not infrequently recognized as such by the patient.

If this is true uræmia, what is the explanation of the many fatal cases of coma without changes in the blood, but with obvious renal disease at autopsy? The answer is that these latter are examples of pseudo-uræmia in whom renal disease is accompanied by changes in the cardiovascular system, and that it is this cardiovascular change which produces cerebral effects leading to coma and death. It is often a matter of considerable difficulty to distinguish between the two groups on clinical examination alone. The pseudo-uræmic group is always characterized by elevation of the blood pressure, whilst the evidences of chemical derangement are slight or absent. The fact that these cases are dependent on changes in the lesser arteries and on diminution of the blood-supply of the brain leads to the fact that changes in the retina are present in most of them, chemical changes in the blood and urine are not conspicuous and may actually be absent. In true uræmia, on the other hand, there may be no elevation of the blood pressure at all, eye changes are often absent, but examination of the blood invariably discloses the true diagnosis.

From the therapeutic standpoint the distinction between these two conditions is of the utmost importance, because in true uræmia the indication is to adopt measures such as protein starvation which may alleviate the chemical condition of the blood, whereas in pseudo-uræmia it is of cardinal importance to bring about a change in the cerebral circulation as rapidly as possible, and venesection, lumbar puncture, and the intravenous administration of hypertonic solutions often become of critical importance. A. M. Fishberg, of New York, who has done so much invaluable work on these questions, has also been responsible for the introduction of many felicitous terms which enable us to understand the modern view. He refers to the cerebral manifestations of high blood pressure as 'hypertensive encephalopathy' and he would have us speak of 'hypertensive retinopathies' in all those conditions where changes of the retina occur in the course of disease or the cardiovascular system include those examples where the kidney is also involved. Surely this is a change well worthy of general adoption. At a time when we know full well that the group of cases in which albuminuria is most conspicuous, that is to say in the nephroses, retinal changes are never observed, it is ridiculous to retain the term 'albuminuric retinitis' for a condition which clearly has no necessary connection with the presence of albumin in the urine.

THE CLASSIFICATION OF NEPHRITIS

I have felt it necessary to bring before you the above considerations because of the confusion between renal failure and true and false uræmia. The classification of nephritis, because I feel that a clear conception of these states is essential for an appreciation of the classification of nephritis which is becoming evolved largely as a consequence of such doctrine.

I hope that I may be forgiven if at this point I interpolate a brief account of classifications of nephritis which have found many adherents in the past, some of which are current at the present date.

It is impossible to approach the subject of classification without reference to the past, and I must remind

you that Bright was exceedingly cautious in avoiding any hard-and-fast differentiation into groups. Study of the medical history of the last century indeed emphasizes the lack of uniformity in teaching, although it was perhaps unfortunate that in the absence of unity of conception individual writers tended to be dogmatic in dividing renal disease into various groups. It was largely as the result of the work of Wilkes and of Bartels that it became customary to distinguish two main varieties of chronic nephritis to which were attached the terms 'chronic parenchymatous nephritis' and 'chronic interstitial nephritis', the former being essentially a condition characterized clinically by dropsy and albuminuria, and the latter one in which there was a small contracted kidney in a patient dying of uræmia or cerebral hæmorrhage without œdema. The supposed occasional transformation of a case belonging to one group into a condition which flung him into the other group has been the cause of bewilderment and despair to generations of medical students. Many names, such as those of Gull and Sutton and of Weigert, might be quoted amongst the pioneers who exposed the futility of this classification; their voices were unfortunately not heard, although the rapid growth of histological inquiry soon made it apparent to the pathologist that there was no justification for the acceptance of it.

The first decade of the present century saw the genesis of a 'functional' classification of nephritis which originated in France following the revival of biochemical investigation, chiefly as the result of the observation of Vidal and his school. This school sought to divide Bright's disease into a group of patients in whom the damaged kidney was unable to excrete nitrogenous substances and hence produced uræmia, with, in opposition to this, a group in which the disease produced failure to excrete chlorides and other salts and hence produced œdema. At the present time it is unnecessary to say very much concerning this classification beyond that it had a transient value in focusing attention on biochemistry, and that the course of time has amply demonstrated not only that many patients could be placed in both groups simultaneously, but that modern biochemistry has rejected the theory that there is a type of kidney essentially incapable of excreting chloride.

To-day we are approaching a classification which has a sound basis of morbid anatomy and is also compatible with the various clinical manifestations of nephritis. Admitting that the widespread body of observers to whom I referred in the opening paragraphs of this paper has not yet reached agreement as to details, it is becoming more and more generally recognized that three great groups are to be distinguished. Of these the central group is constituted by the true inflammatory diseases of the kidney following acute infections. This great group of glomerulo-nephritis may be subdivided into a relatively benign group in which scattered foci of inflammation arise during an acute infection, and a second group in which the inflammation is spread diffusely through both kidneys. This latter subgroup includes all those serious cases of nephritis which, beginning usually as a streptococcal infection, are seen again and again in the medical wards of the general hospitals, and eventually terminate fatally, usually after a very chronic course. In very severe cases the initial effect may be so tremendous as to produce renal failure and death from uræmia. More often an œdema of gradual onset is accompanied by a slowly rising blood pressure, and after waxing and waning for long periods tends to subside as renal failure slowly appears. Death will occur from true uræmia or from cerebral hæmorrhage or from pseudo-uræmia, according as the factor of glomerular destruction or of increasing hypertension is predominant.

Now in sharp opposition to this great group we recognize two other groups which have little if anything in common either with one another or with true inflammatory nephritis. The first of these is that which has

been called 'nephrosis'. Here we have, clinically, an intense albuminuria, with or without œdema, but without either marked hæmaturia, increase in blood pressure, changes in the retina, or any tendency to uræmia. On the histological side we recognize the association of this group with kidneys showing no evidence of change in the glomerulus, but changes, purely degenerative in character, in the renal tubules. The recognition of this group is due largely to the work of Epstein, and if at the present day there is a tendency to reject his belief in the invariably benign character of nephrosis, it remains true that the prognosis in many examples is relatively good. Perhaps the most important lesson from his work has been that whereas even five years ago there was a tendency to say that 'renal œdema was an entirely mysterious phenomenon, it is now becoming agreed in all quarters that diminution of the density and osmotic capacity of the blood-plasma, following leakage of albumin into the urine, is the mechanical factor responsible for the production of renal dropsy. Examples of nephrosis are to be found in cases where the kidney has been damaged by the accidental or suicidal administration of mercurial poisons; another group is that known as lardaceous disease; but many cases have been reported arising apparently spontaneously. The great difficulty concerning nephrosis is that a certain number of these latter cases are found, with the passage of time, to develop hypertension and renal failure. These are examples which probably have been mistakenly diagnosed at the outset, being really cases of diffuse glomerulo-nephritis in which the initial glomerular damage was so slight as to escape recognition.

At the further extremity of the scale we find another main variety, contrasting vividly with nephrosis and constituting the third of the great main groups of renal disease. This is the division which includes all those cases in which the kidneys are damaged by changes in their blood-supply following some generalized vascular degeneration. Perhaps the best name to give to this group is 'ischaemic nephritis'. The outstanding clinical manifestation of these is hypertension, the outstanding feature of their morbid anatomy is sclerosis of the kidneys and spleen, with hypertrophy of the heart. Several subdivisions of this group are becoming recognized, but I do not wish to complicate the story by entering into fuller description of these beyond saying that far and away the most frequent cause of ischaemic nephritis is that mysterious condition which we speak about as 'essential hypertension' or 'hyperpiesia'. I cannot too forcibly remind you that death in this group arises far more frequently from cerebral catastrophe or from cardiac failure than from renal failure; many authorities have stated their conviction that less than 10 per cent of all such patients die of uræmia and renal failure, but many pathologists, finding in the post-mortem room a body with conspicuously shrivelled kidneys, incline even to-day to group all such cases as 'chronic interstitial nephritis'. Very brief histological examination of other organs, such as the spleen, should be sufficient to demonstrate that to regard such cases as primary diseases of the kidney is to fall into grave error. Sir William Gull, many years ago, had occasion to question the conception of the great Bright in this respect. Lecturing on some preserved specimens consisting of a large heart and two contracted kidneys, he said that not these alone but the entire man should have been included in the vase.

I do not wish it to be supposed that there are no clinical difficulties as regards the allocation of certain cases to this last group. True inflammatory disease of the kidney may be so insidious in its onset, and may be accompanied by such widespread arterial change, that hypertension is altogether predominant in the picture, but for every case of true chronic nephritis of this type there are probably 50 in which primary arterial disease is mistakenly classed as chronic interstitial nephritis.

Surgical Treatment of Pulmonary Tuberculosis

By E. BELLINGHAM-SMITH
and

ANTHONY FEILING

(Abstracted from the *Modern Medical Treatment*, Vol. II, p. 527. London: Cassell and Company, 1931)

THE operative treatment of tuberculosis of the lungs includes the performance of artificial pneumothorax, phrenicotomy and thoracoplasty. In artificial pneumothorax we have an important aid to treatment. In cases where the disease is unilateral but not reacting to rest and treatment and advance is rapid, the application of artificial pneumothorax may cause not only a definite arrest in the disease, but also free the patient from all the symptoms of an acute toxæmia. It is further of value in recurrent and severe hæmoptysis, and may be used in conjunction with sanocrysin where the disease is bilateral. It is not absolutely contra-indicated in cases where the disease in the opposite lung is slight. This method of treatment has been further adapted so that a partial pneumothorax has been instituted on both sides in cases of bilateral disease, there being some evidence to show that the gas so introduced tends to collect over the affected area and cause a local compression. The immediate results of the operation are striking. Fever, cough and sputum cease, the pulse decreases, the appetite improves, weight increases and the sallow, hectic appearance associated with toxæmia is replaced by a healthy colour. The ultimate results are not perhaps so easy to determine. Pleurisy with effusion occurs in 40 to 50 per cent of cases, permanent collapse occurs in a limited number, while in others a degree of expansion may occur associated with some resumption of lung function. In still others the expansion takes place with diffuse fibrotic and bronchiectatic changes and adherence of lung to the chest-wall. The dangers of this operation are: (1) pleural shock; (2) penetration of lung, and gas embolism; (3) injury to lung or tearing of adhesions giving rise to a pyopneumothorax, and (4) a rapid extension of the disease in the contralateral lung from overwork induced by the collapse and loss of the unhealthy one.

For the induction of an artificial pneumothorax there are several types of instruments, all based on the same principle. Those in common use are Forlanini's and Lillingston and Pearson's (see diagram). But it is possible by a little ingenuity to improvise one. All that is required is two glass jars, one graduated in cubic centimetres, and a U-shaped manometer fixed on a scale graduated also in cubic centimetres and recording positive and negative pressures. A three-way glass connection, some rubber and glass tubing, three metal clamps, a quantity of sterile wool, some mercuric perchloride solution for the bottles, and a coloured liquid suitable as an indicator for the manometer, complete the requirements. The whole, when fitted together, can be carried in a wooden case. Two needles are usually advised, one for the primary induction and one for the refills; the first is a trocar and cannula with blunt but cutting edge, the second has the pointed bevelled extremity of an ordinary exploring needle. Both have a tap and by-pass tube in the hilt. It will be seen from the diagram that when the needle is in the chest, release of clamp 3 places the pleural cavity in contact with the manometer. At the same time the respiratory movements will be registered by an oscillation of the column of fluid. With the release of clamps 1 and 2 the wash-bottles A and B are introduced into the circuit, and elevation of A will force air out of B into the chest cavity. The quantity of air so transferred is measured by means of the graduations of B.

Before the operation is begun the whole apparatus should be carefully sterilized and examined for leakage,

and the tubing, filters and needle should be thoroughly dried. For induction the patient should be in bed, a preliminary dose of omopon or morphia being given to allay nervous excitability. He lies supine, but turned somewhat on to his sound side so as to bring the site of operation directly uppermost, the head being low in order to reduce the risk of gas embolism. The arm is removed from the sphere of action by stretching it above the head, and letting the hand grasp the bed-rail behind. The usual site for puncture is the sixth space in the anterior or mid-axillary line, for this is shown to be the site most free from adhesions, and also where the lungs show the most marked respiratory excursions. The skin is cleansed, and sterile towels are placed round the area of operation. Novocain is injected slowly into the skin and deeper tissues down to the pleural layer, so as to guard against pleural shock. The needle is

now introduced carefully and gently through the chest-wall as far as the pleura. The trocar of the needle is withdrawn, the tap on the hilt is turned and clamp 3 is released, placing the needle in direct communication with the manometer. The cannula is now pushed through the pleura into the pleural cavity. When the cannula has entered the pleural cavity a negative pressure will be recorded on the manometer and oscillations of the column of fluid through a range of 3 to 10 cm. will be seen corresponding with the respiratory movement. Before the needle enters the pleural cavity care should be taken to warn the patient against coughing. If oscillations do not occur after the needle has supposedly entered the pleural cavity either the needle has not penetrated the parietal pleura, or the lumen is blocked, or the lung has been penetrated.

Introduction into or injury to a vessel will be shown by a positive pressure, or by the presence of blood in the glass connection between the needle and the manometer. If air is admitted before the needle has entered the pleural cavity, surgical emphysema will result, or if it is admitted after the introduction of the needle into a pulmonary vessel gas embolism and sudden death may occur. It is therefore important to be certain that definite oscillations of a negative type are occurring, corresponding to inspiration and expiration, before air is admitted. The introduction of the air is accomplished by releasing the clamps 1 and 2 between the wash-bottles in series and the manometer

and needle in the chest. Air is drawn into the chest from the second bottle B and fluid passes from the first bottle A into bottle B to replace it. By gradually raising bottle A, further air can be introduced. A convenient amount of gas for the first operation is 200 to 300 c.c., but, even so, the essential factor is the manometer reading. If the gas flows in easily and the patient complains of no increasing discomfort this amount can be run in, with the pleural pressure still remaining on the negative side; a lung can be adequately collapsed with the pleural pressure never exceeding 2 c.c. of water. If, however, the pleural space is not free, the introduction of only a small amount of gas will show a manometer reading on the positive side, and may be accompanied by a certain amount of pain and distress. The needle is then withdrawn and the puncture covered with iodine or collodion. Refills will be required two days later and again in three days after the second refill. Thereafter, refills will take place at longer intervals—one week, ten days, fourteen days, twenty-eight days; the time will vary with the degree of collapse secured with the condition of the patient and his reaction to the treatment, and with the rapidity of absorption of gas, which varies very materially with different individuals.

Over-pressure will cause discomfort and dangerous displacement of the mediastinum. On the other hand, a failure to maintain sufficient pressure, with consequent re-expansion of the lung, defeats the object of the operation, and will terminate in the rapid formation of adhesions and compulsory abandonment of the artificial pneumothorax. The degree of collapse can be controlled by careful x-ray observation. During the first few weeks of induction the patient should be at rest; afterwards refills may be undertaken, and the patient need only rest for a few hours following the operation.

Artificial pneumothorax, though indicated by the stage or character of the disease, is not always feasible on account of adhesions between the visceral and parietal pleurae. In some of these cases where adhesion is not dense, division of the adhesion may be undertaken by cautery, access to the chest and localization of the adhesions being obtained by the thoracoscope. Where the adhesions are mainly basal, a preliminary phrenicotomy may be undertaken. This causes a paralysis of the diaphragm on the same side, enabling the base of the lung to collapse. It has been used by itself as a means of promoting rest in the infected lung in very acute, rapidly progressive lesions where pneumothorax and thoracoplasty, on account of a bilateral infection, were contra-indicated; but it clearly cannot cause that complete collapse and immobility which is provided by artificial pneumothorax, or, as we shall show later, thoracoplasty.

Phrenicotomy, or a more extensive removal of the phrenic nerve, exsiccation, has certain further advantages when performed in association with artificial pneumothorax. There is less likelihood of pleural effusion. The smaller pleural cavity eventually left better accommodates the contracted lung, and there is less liability to reactivation of tubercle in the compressed lung and, when the pneumothorax is discontinued, to re-expansion of cavities which have been previously closed. For when pneumothorax is discontinued almost immediate adherence takes place between the lung and the chest-wall. Such adhesion, in conjunction with the constant contraction set up in the lung itself by the fibrous tissue formed during the collapse period, along with respiratory movement, will tend to stretch the fibrous scar-tissue around areas of tuberculosis and cavitation. There is a further tendency to the formation of bronchiectasis in the remaining healthier lower portions of the lung, which phrenicotomy may prevent, while its further service is shown in correcting the mediastinal displacement which follows partial re-expansion. Where pneumothorax can be successfully maintained the final difficulty lies in knowing when to stop. Reactivation has taken place in certain cases after considerable periods have elapsed.

It would seem wise therefore, when possible, to persist in this treatment for a period of at least two years. Many authorities advocate three to five years.

When for reasons given above, artificial pneumothorax has to be abandoned, or when in the fullness of time it is discontinued and reactivation occurs, or bronchiectasis or chronic empyema makes life unbearable, there arises the question of thoracoplasty. This operation has for its purpose the same object as artificial pneumothorax, viz, the compression and putting at complete rest of the diseased lung. The indications for its performance are suggested above, and the conditions under which it is carried out are the same as those for phrenicotomy and artificial pneumothorax, namely, advanced pulmonary tuberculosis in one lung with little or no infection in the other lung. It may be undertaken alone as a paravertebral thoracoplasty of ribs 1–11, or as a partial resection of ribs 1–7 with radical phrenicotomy. As a rule, phrenicotomy is preferably performed before either the complete or partial operation. The operation itself consists in the extra-pleural resection of 1 to 6 inches of each of the first eleven ribs. This is carried out in either one or two stages. Its effect is to produce a collapse of the chest-wall, with rigid fixation and a complete and permanent shrinkage and compression of the diseased lung. The immediate mortality from this operation is less than 2 per cent, the delayed mortality from causes indirectly concerned with the operation about 13 per cent. When one considers that the type of case required for this operation is usually advanced and the eventual prospect hopeless, such a mortality does not appear to be excessive. Alexander, in his book *The Surgery of Pulmonary Tuberculosis*, analyses 1,159 cases operated upon in the last seven years. Of these, 36.8 per cent were completely cured or clinically cured, 24 per cent improved, 5 per cent were living but unimproved, and 33 per cent had died. It is early to claim a permanent cure for the cases reported as cured, but the degree of success attained was a remarkable achievement in view of the hopeless character of the stage at which the disease had arrived.

Influenza

By R. COVE-SMITH, M.A., M.B. (Cantab.)

M.R.C.P. (Lond.), D.P.H.

(Abstracted from the *Medical Press and Circular*, New Series, Vol. CXXXV, No. 4891, 1st February, 1932, p. 94)

SIGNS AND SYMPTOMS

THE story of onset given by the majority of patients is surprisingly similar, and runs as follows: First of all a feeling of weariness, followed by dryness or soreness of the throat. In four to five hours this is added to by an aching in the limbs; the arms feel heavy; the legs ache, and the effort of taking a deep breath or of coughing causes a pain beneath the shoulder blade, or round the lower ribs. This is often accompanied by a feeling of constriction round the head, followed by throbbing in the temples, and a pain running up behind the jaw into the post-aural region. Intense weariness and disinclination for effort become evident, and then suddenly the patient feels hot and flushed, perspiration seems imminent, but instead a cold frozen feeling, a shivering attack, or a rigor supervenes. Three or four of these may follow each other at short intervals. It is usually about this time that the patient retires to bed and the doctor is called in. On examination the patient looks somewhat anxious, with furrowed brows, slight photophobia, and is disinclined to read. Most patients are limp and lethargic, and quite content to curl up. The body pains tend to increase, and shift about from place to place—arm, shoulder, calf, hip, etc.—but frequently settle finally in the loins and lower rib region. The temperature is not considerably raised, in the majority of cases being about 101°–102°F. A few

endeavouring to lower the patient's temperature by salicylates or aspirin, though the latter may be given with caution to ease the headache or body pains. Frequent mouth washes with potassium permanganate (1:4,000), and trochiscus potassii chloratis, gr. 5, four-hourly, are useful, with a view to limiting the multiplication of pyogenic organisms always present in the mouth and nasopharynx. Local applications to the upper part of the chest and neck in the form of poultices and liniments are useful for allaying the cough and substernal uneasiness. Tinctura benzoini composita (four parts) with menthol or eucalyptus (one part), as an inhalation, with the administration of tinctura camphoræ composita, may be useful in the treatment of a very irritable cough. The latter should never be used where there is any implication of the smaller bronchial tubes, with or without cyanosis, and the former avoided in the severer types of influenzal laryngitis and tracheitis where there is dyspnoea from swelling of the mucous membrane of the glottis, for œdema of the glottis can develop.

BRONCHITIS (DIFFUSE BRONCHITIS, LOCALIZED BRONCHITIS, SEVERE PURULENT BRONCHITIS)

With the destruction of the ciliated epithelium of the larynx and trachea, these are laid open to invasion by streptococci and pneumococci, and other inhabitants of the upper respiratory passages. This may result in a spread of inflammatory processes down the main and smaller bronchi, and the clinical picture of diffuse bronchitis.

In the earlier stages of the bronchial affection the cough is dry, and expectoration scanty and viscid. If the smaller bronchi are involved the cough becomes more distressing, and may be paroxysmal. Dyspnoea may be a troublesome feature, and cyanosis marked; this being due to swelling of the mucous membrane and accumulation of debris in the tubes. This swelling and exudation in some influenzal epidemics has been so extensive and severe as to largely occlude even the main bronchi. After a few days the sputum becomes more abundant and mucopurulent, and in the severer cases may contain blood. At this stage, with no further extension of the inflammatory process, the dyspnoea and subjective tightness of the chest become relieved, but the expectoration and cough may continue with diminishing severity for several weeks.

With only the larger bronchial tubes involved there will be no objective signs, but it is more common to have more extensive involvement of the smaller bronchi with dry râles throughout the lungs though more marked at the bases. With resolution of the bronchitis these râles become coarser and moister, and clear up in a few days or so. With extension of the inflammation, these râles become finer and stickier, and approach in character to crepitations—crepitant râles: this signifies the onset of capillary bronchitis or bronchiolitis.

It may be expedient to mention here that influenza can be complicated by a localized bronchitis. Of course, localized bronchitis is usually symptomatic—at the apex of tuberculosis, at the base of hypostatic congestion. It is wise even in the localized bronchitis of influenza to have in mind an area of pulmonary tissue of inferior resistance, the potential seat of tuberculosis, or even its present nidus flamed into activity by the catarrhal process. The onset of pulmonary tuberculosis has often been associated with, and even ascribed to, an attack of influenza.

With this diffuse bronchitis, alkalis in the early stages and stimulating expectorants later both have their place in aiding the expulsion of infected material from the lung. Tinctura benzoini composita inhalations are useful in selected cases, with no more than a little respiratory embarrassment. Counter-irritants to the chest give subjective relief to the sense of constriction and tightness in many cases. Oxygen will relieve the respiratory distress associated with cyanosis in those cases in which this is not due to further extension of the morbid process leading to exudation into the pulmonary alveoli.

It has been the common experience in the recent epidemic of influenza complicated by bronchitis, for cough to persist for weeks after the patient is up and about. This is due to the slow recovery of the bronchial mucous membrane, which is always so severely damaged in these cases. Especial care is needed in the convalescence of influenzal bronchitis for this reason, and I always advise that the patient be confined to an even temperature for a week at least after the disappearance of all signs from the chest.

CAPILLARY BRONCHITIS, BRONCHO-PNEUMONIA AND HELIOTROPE PNEUMONIA

When the smallest bronchi and bronchioles become inflamed, the terminal alveoli almost invariably become involved, for little swelling of the bronchiolar wall is sufficient to occlude the lumen of the tube with the production of an area of lobular collapse. The inflammatory process then extends into some or all of these areas, and broncho-pneumonic consolidation results.

Clinically the implication of the finer tubes and alveoli is signified by a further rise in temperature, greater difficulty with respiration, often associated with a marked degree of cyanosis, and an irritating shallow and persistent cough. The earliest findings on examination are the presence of crepitations in contrast to the bronchitic râles of the former stage. They appear often as an inspiratory burst of abundant fine and rather consonating, moist sounds. The lobular consolidation which goes hand in hand with the bronchiolitis may give rise to no further signs, and as such has to be presumed, as the autopsy table so often shows. Compensatory emphysema may be more than sufficient to overcome the dullness which otherwise would be elicited, and, indeed, a hyper-resonant note is not uncommon. It is common to find different signs simultaneously in various parts of the thorax, sometimes on one side, sometimes on the other, and they may alternate with one another in the protracted forms.

Of course, the degree of severity of this condition varies, on the one hand, with a few scattered areas of bronchiolitis and broncho-pneumonia with rapid resolution, and, on the other, with a progressive diffuse inflammation associated with a dyspnoea so violent that the patient suffocates. This is sometimes called suffocative catarrh; it is in its acutest form characterized by extreme prostration and a heliotrope tint of the skin and mucous membranes, usually followed by death in from twelve to twenty-four hours in spite of all forms of treatment—the so-called 'heliotrope pneumonia'.

Therapeutic efforts must be directed chiefly to sustaining the patient's strength and combating the toxæmia and circulatory failure. In regard to the first of these, good and efficient nursing can never be overstressed. An easily digested food with carbohydrate should be given in small quantities and frequently. Alcohol is useful, and should be pushed to its physiological limit. When the lungs are rapidly filling with serum and mucus a dose of atropin sulphate (gr. 1/75) will often arrest the secretion, and tide the patient over a critical period; stimulating expectorants have also their place in the stage of free secretion. Narcotics may have to be resorted to—rest is all-important—but any form of opium should be strictly avoided. No drug should be given unless there is a clear necessity for its use—they can help the patient, but they cannot cure him.

BRONCHIECTASIS, BRONCHIOLITIS FIBROSA OBLITERANS, ABSCESS AND GANGRENE

The bronchioles lack the protective loops of cartilage of the bronchi, and when they have been involved in a severe inflammatory process their muscular wall undergoes in places degeneration and atrophy and the resultant weakening of their walls is followed by dilatation and bronchiectasis.

Bronchiectasis is more liable to develop in those cases in which the sputum has been particularly purulent and foetid, and in those in which the bronchiolitis has run a protracted course.

Sometimes, but rarely, organization of the bronchiolar and pneumonic exudate takes place by a fibroblastic proliferation from the alveolar and bronchiolar walls, leading to a patchy but severe fibrosis of the lung. Pathologically, this condition is known as bronchiolitis fibrosa obliterans; clinically, it is included under the generic term—unresolved pneumonia. It necessarily results in the ultimate loss of function of whole groups of alveoli, and is liable to be followed by persistent dyspnoea and cyanosis. It tends to occur in the more debilitated patient and in those in whom the bronchiolitis has persisted for an unduly long time.

Multiple small pulmonary abscesses and areas of gangrene are not uncommon in the severer types of broncho-pneumonia complicating influenza, but death supervenes in the broncho-pneumonic stage. A solitary large suppurative focus or pulmonary abscess is extremely rare, and should be suspected when, after the resolution of the general broncho-pneumonic process, symptoms of localized pus formation, and perhaps with signs of an area of pulmonary consolidation, persist. Clubbing of the fingers can occur very early in cases of lung abscess.

LOBAR PNEUMONIA AND INFLUENZA

Lobar pneumonia is not usually regarded as a manifestation of influenza, and when compared with the incidence of broncho-pneumonia it is negligible; but I have seen a case recently in which it suddenly developed during the convalescent stage of a mild influenzal bronchitis.

PLEURISY, PLEURAL EFFUSION AND EMPYEMA

Pleurisy occurs sometimes quite early on in the respiratory type of influenza. It means that pyogenic organisms have gained entrance to the bronchial lymphatics, and have spread down through the lymphatics of the pulmonary parenchyma to the visceral pleura of the lung. The common signs of pleurisy are found usually associated with pain; effusion may follow.

Effusion is more likely to follow in those cases in which pleural inflammation has occurred over areas of broncho-pneumonic consolidation in the lung. In some cases it is most important to realize that the bronchitis and patchy broncho-pneumonia are quite insignificant, and an empyema insidiously develops and becomes the chief factor in the disease. In other words, pleural effusion may develop and become purulent when consolidation in the lung has been minimal, and has escaped the notice of the medical man in attendance.

The presence of fluid in the pleural sac is suggested by a persistence of the patient's temperature, with resolution of the inflammatory process in the lung. The more useful sign is the development of a duller note usually at one base or the other, with feeble or absent breath sounds over this dull area. Repeated careful exploratory punctures are advisable where the signs and symptoms would suggest the presence of fluid in the pleural space.

In contradistinction to the empyema fluid aspirated in lobar pneumonia, which is usually frank pus at the time of the first puncture and contains many organisms (pneumococci), the effusion in influenza is often of a sero-fibrinous nature, or slightly opalescent. A few organisms may be found in smears from the fluid, but cultures from the same fluid may be sterile. The streptococcus, pneumococcus, and less often the influenza bacillus, are commonly found. These effusions may become purulent, but, on the other hand, can absorb and clear up sometimes with repeated puncture. An empyema operation is inadvisable until the fluid is obviously purulent, and until this occurs repeated pleural puncture may be necessary in large effusions to relieve any respiratory distress, and in the smaller effusions may obviate the necessity for rib resection altogether.

In this short article I have tried to indicate that the primary lesion at the root of the whole matter in influenza is a naso-pharyngeal catarrh and tracheo-bronchitis, which allows other organisms an easy access

to the pulmonary tissue. In the dreaded pandemic cases the virus increased in virulence results in a hæmorrhagic œdema of the lung with a blood-stained, watery fluid pouring out of the bronchi, much as it did in the first cases of gas poisoning in those early days at Ypres; no known treatment in these cases is of any avail. I have attempted to show in the complications following the tracheo-bronchitis that through their whole course there is a simple basic theme which is played upon and altered by the different secondary invading organisms, and the variable resistance of each patient. I have dealt as far as possible with the inflammations in the lung that become chronic, and would stress again the often peculiar insidious development of empyema.

A realization of the course that the influenzal pulmonary state may take, and the common course that it does take, will lead us to preventive measures at different stages, and treatment on more rational lines at the inception of each stage.

The Prevention of Colds and Other Respiratory Infections

By DAVID THOMSON

and

ROBERT THOMSON

(Abstracted from 'The Common Cold', the *Annals of the Pickett-Thomson Research Laboratory*, Vol. VIII, December 1932, p. 657)

THE various methods used for the prevention of colds may be briefly enumerated as follows:

(a) *Measures which reduce the chances of infection.*—These are the avoidance of crowded places during epidemics, avoidance of patients and sick-rooms, avoidance of dust-laden atmospheres, and avoidance of kissing. The chances of infection can also be reduced; not so much by trying to avoid it, but by measures which insure better ventilation of public places of amusement, of schoolrooms, of factories, offices, and of school dormitories. Coupled with better ventilation we must have more space so that the individuals are less crowded whether in the schoolroom, the dormitory, or the factory. This provision of more space reduces the chance of droplet infection.

Other measures which reduce the chances of infection are the sterilization of the air by formalin vapour, etc.; sterilization of fomites, towels, handkerchiefs, etc.; the wearing of masks by the patients, isolation of patients, and the exclusion of carriers.

Probably one of the most important methods of reducing the chance of infection is by means of gargling the throat and treating the nasal passages with some mild antiseptic once or more times daily, more especially during epidemics. There has been a great deal of controversy over this procedure, but it seems to us extremely reasonable to suppose that just as we can prevent infection with venereal diseases through the application of antiseptics soon after exposure so should we be able to prevent droplet infection from respiratory diseases by gargling and washing out the nasal cavities with weak antiseptics.

No one objects to gargling, but the practice of nasal douching has been strongly condemned by many nose specialists because of the danger of thereby causing infection of the nasal sinuses and the middle ear. There can be no doubt that nasal douching by means of forceful injection as with a Higginson syringe is dangerous and should never be done. All such dangers, however, are avoided if we sniff the antiseptic lotion up the nose, because this sniffing produces a negative pressure and avoids the danger of forcing septic material into the sinuses or into the Eustachian tubes. The other danger is the use of too strong antiseptics because these damage the delicate mucous membranes and render them more liable to infection than before. If, however, we use extremely weak and non-irritating antiseptics and sniff them up the nose, we consider that this, combined with gargling, is very good practice if carried out night or

morning or soon after any exposure to infection; more especially during the prevalence of epidemics.

(b) *Measures which increase resistance to catarrhal infections.*—Probably the most important of such measures is the remedying of inherent defects in the nose, such as the removal of polypi, adenoids, and other unhealthy obstructions. The removal of obviously diseased tonsils is also important. There has been some opposition in recent years to the wholesale removal of tonsils and adenoids such as has been practised for some years past, but in our opinion this is only the swing of the pendulum to the opposite extreme due to the fact that it has been overdone in the past. We think that there can be no doubt that grossly enlarged and unhealthy tonsils and adenoids should be removed. There has also been too much tendency to operate on the nose, but if moderation and discretion is used in this matter there is little doubt that the patient will derive great benefit from the surgical treatment of gross defects in the majority of instances.

(c) *Dietetic methods of increasing resistance.*—There can be no doubt that proper feeding increases the general resistance to disease. No definite rules, however, can be laid down for every person. Some individuals eat too much and others eat too little. In general, one would recommend a well-balanced diet with a sufficiency of vitamins. Rickety children are susceptible to colds, so a sufficiency of vitamins A and D are essential. Cod-liver oil was formerly administered for this purpose, but there are now many substitutes and vitamin extracts on the market.

(d) *Avoidance of constipation.*—We believe that the general health, and therefore the bodily resistance, can be greatly improved by keeping the bowels cleared out two to three times a day. The importance of this is not fully realized either by the medical profession or by the public. The best way to keep the intestine clean is to clear it out several times a day. This is vastly superior to the use of so-called intestinal antiseptics. Some medical men seem to think that purgatives are to be avoided. In our opinion they should be used continuously by many individuals, and the dosage does not require to be increased if the type of laxative is changed or varied from time to time. We know a very healthy and active old lady in Scotland, aged 98, who has used powerful purgatives more or less constantly for a period of more than 50 years. Her son, who is a doctor, aged 60, had constantly warned her for many years on the dangers of purgative medicines, but she refused to take his advice, and now this doctor himself is a convert and a firm believer in his mother's teaching in this respect. In these days of overeating and sedentary living it is sound common sense to clear the bowels out thoroughly at least twice a day, and there are innumerable excellent laxatives for this purpose.

(e) *Ultra-violet light.*—We believe that ultra-violet radiation is an excellent thing during the long, sunless winter months, and that this is an aid in increasing our resistance to colds.

(f) *The importance of warmth.*—We have seen that chill and any drop in the temperature of the atmosphere predisposes to colds. It is sound common sense, therefore, to keep ourselves adequately warm during cold weather by means of a sufficient amount of clothing and by sufficient warming of the houses and rooms in which we work. Those who advocate that we should go about shivering with the idea that we are hardening ourselves, and that this is correct because some savages do so, are not level-headed, but should be regarded as cranks. Their advice is quite wrong for the average sedentary worker.

(g) *General hygiene, exercise, fresh air, baths, etc.,* are all to be strongly recommended, provided that discretion is used, and so long as it is remembered that it is possible to be over-enthusiastic and to overdo things. Violent exercise after middle age or too prolonged exertion will do harm, and cold baths do not suit many people. On the other hand, very many people

living in towns take far too little exercise and become exceedingly flabby. The most important muscles in the body to exercise are the abdominal muscles. It is far more important for health that the abdominal muscles should be strong and firm than that the biceps should be developed.

(h) *The importance of the early eradication of all septic foci.*—We have now finished our eighth volume of these Annals, and in the course of our studies we have consulted about 15,000 research papers. In pondering over this enormous mass of medical research, it seems to us that the most important fact which stands out above all others is the danger and far-reaching effects of septic foci in any part of the body. Any septic focus on the skin is immediately seen by the patient and as a rule is attended to at once. When, however, similar small septic areas occur around the teeth, or at the apices of the teeth, or in the throat or tonsils, or in the nose, or in the intestine, they are not as a rule noticed, and remain unattended. Nevertheless, it is these small initial spots of sepsis which spread and lead to systemic infection. They are the beginnings of long-continued chronic illness and the cause of premature decay and death. A tiny focus of sepsis no bigger than a split pea around or at the apex of a tooth may start a long-continued and persistent fibrositis in some distant part of the body. Similar septic foci in the gums and mouth may set up repeated attacks of tonsillitis and catarrhs of the respiratory tract. It is in these small septic foci that the bacteria of respiratory catarrh lurk, and they are ever ready to spread rapidly from these unhealthy areas when the resistance of the body is lowered. We have already pointed out at length the far-reaching dangers of sepsis in the nasal sinuses, and have shown that these septic foci, which are most persistent if not attended to, cause repeated reinfections of the whole respiratory tract leading even to bronchitis and bronchiectasis. The situation will be more easily grasped if we think of an ordinary tree. The average tree as a rule dies of rot, and that rot commences as a small area usually due to an injury to the bark. This gradually spreads if unattended to, and after the course of years causes the final death of the tree. This same and simple truth applies equally to the human body, and we cannot urge too strongly upon medical men and upon the general public the importance of searching for and eradicating at once all small foci of sepsis or suppuration in any part of the body. The most common site for these is in the mouth and around the teeth. Great advances have been made in detecting septic foci about the teeth by means of x-rays, and full advantage should be taken of this at frequent intervals or at any rate at least once a year. Of equal importance is the radiological examination of the sinuses of the nose. Much human suffering and disease could be avoided by such intelligence and foresight, and the healthy constitution to which we aspire could be prolonged for a much greater time. Above all, remember that cleanliness and the diligent eradication of small septic foci in the mouth, teeth, and nose are even more important for health than the much lauded importance of fresh air, exercise, and bathing of the outside of the body.

(i) *The importance of cleanliness in the prevention of colds.*—We have seen that colds are caused by certain species of pathogenic bacteria. The greatest enemy of all pathogenic bacteria is cleanliness and hygiene in its widest sense. We have already pointed out the great importance of cleanliness and hygiene with regard to our bodies.

The importance of bathing so as to keep the skin clean has long been preached, but we have pointed out the still greater importance of scrupulous care and cleanliness with regard to the hidden and unseen recesses of the body, namely, in the mouth, nose, and elsewhere.

Equally important is the hygiene and cleanliness of our clothing and of the various objects which we use in daily life. Just as important also is the hygiene of our surroundings; thus scrupulous cleanliness is required

in the home, in the school, the factory, the office, the shop, the bus, the theatre, etc., etc. This cleanliness requires ample ventilation, frequent washing and extraction of dust.

Dust is an important factor in the causation of colds. The principal cause of dust in the streets of London is the excrement of horses and dogs. It seems to us that the London County Council and other town councils should do something active about this matter. It is just as important as the problem of pollution of the atmosphere with smoke. People who keep dogs in cities should be compelled to provide special water-closets for them in their own houses. Horses should now be disallowed in all large cities, for not only are they the chief cause of pollution of the streets, but they interfere very greatly with the normal motor traffic.

The keeping of domestic animals, such as dogs and cats, is a problem which requires very much investigation. So far we know nothing with regard to the part played by animals in the genesis and spread

of epidemics of colds. Hoyle's recent work, which clearly shows that mice are highly susceptible to several of the bacteria which cause colds in man, is very significant. Highly susceptible animals are apt to pass these bacteria back to man in a much greater state of virulence. Who knows, therefore, whether or not the pneumococci are coming back to us from mice through the agency of cats?

It is important, therefore, that all houses should be constructed so as to be vermin-proof, and it is important that our domestic animals should be kept as clean and as healthy as ourselves. Animals of the rodent type are of enormous importance in the spread of plague; they may be of equal importance in the spread of the common cold. We have found streptococci and Gram-negative cocci of the catarrhalis group in fleas which have been fed on rats. Serious investigations are required into all these matters, more especially as the common cold is one of the greatest scourges of civilization in the temperate climates.

Reviews

THE MEDICAL ANNUAL: A YEAR BOOK OF TREATMENT AND PRACTITIONERS' INDEX.—Edited by C. F. Coombs, M.D., F.R.C.P. (the late), and A. R. Short, M.D., B.S., B.Sc., F.R.C.S. Fifty-first Year. 1933. Bristol: John Wright and Sons Ltd., 1933. Pp. civ plus 628. Illustrated. Price, 20s.

ONE cannot help being re-impressed each year with the vital importance of this publication to the whole medical profession, and therefore, indirectly, to their patients. By subscribing each year to the *Medical Annual* and devoting a few evenings to its study the practitioner who takes in no medical journal is provided with an opportunity of keeping himself up to date; the man who does receive and read a few medical journals will never fail to find something new with which his journals have not dealt; and the specialist who devotes the best part of the year to the study of his particular subject will receive very considerable benefit by reading up the advances that have been made during the year in other branches of medicine and surgery.

The year has not seen any very striking advances, but steady advances have been made in all branches of medical science. Contemporary history is always difficult to write; advances that seem important to-day may to-morrow be shown to have been steps taken in the wrong direction, or may be forgotten in the more rapid advances that follow; nevertheless, it seems possible that 1932 will be remembered for the introduction of the first really successful synthetic substitute for quinine. This is a subject which is of much greater importance to us in the tropics than to those in the country where this book is published, yet it is a matter that has been given considerable prominence. In fact the various advances in tropical medicine, and more particularly the work done in this country, are always dealt with very fully in the *Medical Annual* each year, and this year is no exception.

Anæsthetists have been very much awake this year and a number of papers have been contributed which place the subject of premedication on a sound footing; nambutal appears to be the most favoured drug in Great Britain. Avertin is still probably the most widely employed of the basal anæsthetics and its dangers, particularly by causing respiratory depression, are said to be controlled completely by the use of coramin.

The effect of the stimulus given to the study of anæmia by the introduction of liver treatment some few years ago has not yet worn off, and the advances that have been made are being consolidated. From an economic point of view the introduction of fish liver in the treatment of the anæmias that respond to liver

treatment is an important one, particularly in England and in many parts of India where fish is comparatively cheap.

The 'diathermic knife' is adopting fresh forms each year and extending its scope. There is now a very ingenious, though very expensive, instrument for transurethral prostatectomy. One sees the advantage of this route in the case of the elderly patient, but the instrument must require very expert handling and its use can scarcely extend much beyond the large city hospitals, so that this particular advance will be of no more than academic interest to 99.9 per cent of the readers of the *Medical Annual*. To mention only such matters is to give wrong impression of the utility of the publication; however, if the general practitioner turns over the next page he will find himself back at his own level with two very practical pages on the subject of the treatment of pruritis ani.

Sialography was a closed book to the reviewer until this year, but one sees the possibilities in the method of 'visibilization' of the salivary ducts by the injection of lipiodol into them. This technique cannot be required very often, but one can imagine that the surgeon would obtain invaluable aid from it in a case of salivary fistula.

Another very useful feature—and I am afraid that this must be the last we mention—is the section devoted to new medical and surgical appliances; our readers will recognize a few of these as having appeared in our 'notes' section during the year.

In view of the fact that medical books appear to be getting more and more expensive each year one cannot help being surprised at the extremely reasonable price of this publication; for fifteen rupees, which I suppose will be the price in this country, no better value could possibly be obtained.

MINOR MALADIES AND THEIR TREATMENT.—By L. Williams, M.D. Sixth Edition. London: Baillière, Tindall and Cox, 1933. Pp. xiii plus 420. Price, 10s. 6d.

DR. LEONARD WILLIAMS is *par excellence* the writer for the general practitioner. He was for many years the editor of that very valuable practitioners' journal, the *Medical Press and Circular*, and since his retirement from this post he has contributed regularly to the paper. Many of his articles have been reprinted, almost word for word, in our Current Topics section, so that he needs little introduction to our readers.

In the introduction to one of the earlier editions of this book the author says that when he was first qualified

he knew a great deal about all the diseases that very few of his patients ever seemed to get, but found that he knew practically nothing about the complaints from which they all suffered, and, failing to get any help from textbooks, he determined that, when his experience warranted it, he would write a book for the use of the general practitioner. He has done; and that book has now been reprinted eleven times in English and once in Spanish.

Dr. Leonard Williams is an extremely pleasing writer; his discourse on the social customs that lead to the development of constipation—a discourse which might well be headed 'the constipated rake's progress' or 'the seven ages of constipation' and which should entitle the author to a place in the National Biography beside Williams Hogarth and Shakespeare—may be taken as a good example of his vivid style. But this chapter is of course written mainly for the European, and the author has in this particular chapter fallen into an old trap. In discussing the evil influence of the European pattern of water closet, he banteringly accuses the manufacturers of being the cause of much constipation. If Dr. Williams were to visit a water-closet maker's factory in England he would find a very large selection of 'eastern pattern' closets on which he could do all the crouching that he wanted. Further, if he came to this country and if he could see through brick walls, he would see not only 'savage man perforce adopting the crouching attitude' but Sanskrit scholars, merchant princes, and world-famous scientists also crouching over Doulton 'bathroom requisites' which would not disgrace the most modern marble-tiled bathroom of the Hollywood 'star'. The fact that constipation is very common amongst the 'crouchers' in this country does not of course detract from the force of the writer's argument.

This criticism is entirely irrelevant, but unadulterated praise, which would be the only alternative, makes sickly reading. The book is not primarily written for this country, but the practitioner in India will nevertheless find it an invaluable guide to the treatment of the everyday ailments of his patients, colds, headaches, indigestion, neuralgias, etc., and we have no hesitation in heartily recommending the book.

A SHORTER ORTHOPÆDIC SURGERY.—By R. Brooke, M.S., F.R.C.S. Pp. 150. With 126 illustrations. Bristol: John Wright & Sons, Ltd., 1932. Price, 10s. 6d.

A SHORT summary of a branch of surgery appears to be one of the most difficult of all books to write, to judge from the mixed reception accorded to several recent efforts. It is made more difficult when the author writes for two different classes of readers, as in the present case. Mr. Brooke aims at supplying the masseuses attached to his hospital with an account of the operative and other treatment carried out in his department on the patients who pass to their care after discharge; he also intends the book for the use of house surgeons. For the latter class of reader the book may be found useful, as it gives a good practical account of many orthopædic conditions—some common, some rare—but sadly restricted in scope by the arrangement of the book on anatomical lines, so that the conditions affecting the skeleton as a whole, such as rickets, osteo-myelitis and bone tumours are not mentioned, nor is there any account of the general pathology of tuberculosis of bones and joints, rheumatoid and gonorrhœal arthritis or of such important conditions as anterior poliomyelitis, spastic diplegia and lesions of the peripheral nerves which supply so many cases for the orthopædic surgeon. For the masseuses the style of the book is too difficult, too much knowledge is assumed and some of the subjects dealt with are above their heads. What interest have they for instance in operations for reconstruction of ruptured cruciate ligaments, a rarely performed operation which was surely introduced by Hey Groves and not by Gallie, to whom it is attributed? Grafting the astragalus on

to the upper end of the femur to fill up a defect left by an acute epiphysitis is a curious procedure, of which the masseuse is not likely to see many examples, she will however be required to treat many cases of stiff joints and adherent muscles or tendons, following injuries or inflammatory conditions, and for this she will get no help from this book; even the treatment of simple sprains is not mentioned, and there are only a few lines on the non-operative treatment of osteoarthritis of each joint. On the other hand many of the sections are good and practical, notably those on congenital dislocation of the hip, internal derangements of the knee joint, flat-foot, congenital club-foot, tuberculosis of the spine and plaster-of-Paris technique. The publishers have maintained their usual high standard of production the illustrations being exceedingly good and well-chosen.

W. L. H.

OFFICE SURGERY.—By F. Beekman, M.D. London: J. B. Lippincott Company, 1932. Pp. xxi plus 402, with 94 illustrations. Price, 21s. Obtainable from Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 15-12.

THERE have appeared at various times a number of books on minor surgery; many of these have been excellent, but this does not mean that there was no room for other books on the same subject. The subject was a very suitable one for the 'Everyday Practice Series', and the author appears to be a man of very considerable practical experience who has the imagination to be able to place himself in the position of the inexperienced and to realize what details will be most valuable to him. The title of the book challenges comment, and, although the author professes to have chosen it because he considers that all surgery is major surgery, we feel that this is a quibble, but that the author, having found that all the changes (manual, handbook, textbook, etc.) had already been rung on the minor surgery theme, was faced with the necessity of breaking new ground; his choice is not a happy one for the British reader, as we do not use the word 'office' in the sense that it is used in America.

The book covers the usual range of minor surgical procedures. The descriptions are clear and the diagrams are useful; it is a common mistake on the part of American writers to overdo the illustrations and occupy space by quite superfluous diagrams and photographs; in this instance this criticism cannot be made.

The book will be found very useful by both students and practitioners in this country where dispensaries and surgeries (or offices) are very modestly equipped.

THE PRACTITIONERS LIBRARY OF MEDICINE AND SURGERY. Volume III. Practice of Medicine. New York and London: D. Appleton and Company, 1932. Pp. II plus 1400. Illustrated. [Available from Messrs. Butterworth and Co. (India), Ltd., Calcutta, the sole agents in India.] Price, Rs. 37-8 per volume. (The set is to be completed in twelve volumes and index.)

VOLUME III of the Practitioners Library is a book on general medicine; nervous diseases have, however, not been included as these will be dealt with in a later volume. The writers are either well-known teachers in different universities in the United States or the occupants of important positions in large institutions in that country. A nice balance has been observed in dealing with the various subjects and aetiology, pathology, diagnosis and treatment are each accorded their fair share of space. Generally speaking, the usual practice has been followed in the allotment of space to the various subjects, but the editor has not followed this slavishly, and certain diseases which have been decreasing during recent years are accordingly dealt with more briefly. An example of this is typhoid, a subject which thirty years ago occupied about 10 per cent of a textbook of general medicine; it is dismissed almost summarily in 26 pages. However, reading

through this chapter one finds it difficult to say what has been omitted. More space has been given to allergic diseases, diseases of the endocrine glands, and other diseases which are assuming a greater importance in view of the advances that have been made in recent years.

The tropical diseases section is as satisfactory as one could expect in a book on general medicine. The editor has been fortunate in getting Professor Hegner to write on most of the diseases that come under this heading, so that, where he has been allowed the space, full justice has been done to the subject, but some diseases, especially those which do not occur in the United States, have been treated somewhat parsimoniously; leishmaniasis is only allowed one very small paragraph. In certain instances there might have been a better liaison between editor and the contributor; for example, we do not believe that Professor Hegner could spread himself on the subject of ascariasis only to the extent of three-quarters of a page; he might with advantage have written another page on the subject, and thereby filled the page which is now blank without adding to the bulk of the book. However this volume maintains the high standard of the series.

We have been requested to state that Messrs. Butterworth and Company will be pleased to supply this complete work on the instalment system, full particulars of which may be obtained from them on request.

PRINCIPLES AND PRACTICE OF OBSTETRICS.—By Professor Joseph B. DeLee, A.M., M.D. Sixth Edition. Thoroughly Revised. Philadelphia and London: W. B. Saunders Company, Ltd., 1933. Pp. xvi plus 1165 pages, with 1,221 illustrations, some in colours. Price, 60s.

The fifth edition of this book on obstetrics maintains the high standard of the previous edition. The general plan is as before; part I is devoted to the physiology of pregnancy, labour and the puerperium, part II to the pathology of pregnancy and labour, and part III to operative obstetrics.

The work is designed, as the author says in the preface, to supply the needs of the student and at the same time provide a wealth of instructive detail and illustrations for the practitioner making an ever-present help in trouble. In this, the author has succeeded and is to be congratulated on the production and the very thorough revision of this monumental work, which contains all the very latest accomplishments in obstetrics. We can commend this book to those who prefer a large treatise, but it will probably appeal more to the qualified man than to the undergraduate.

C. L.

THE COMMON CAUSES OF CHRONIC INDIGESTION: DIFFERENTIAL DIAGNOSIS AND TREATMENT.—By T. C. Hunt, B.A., D.M. (Oxon.), M.R.C.P. (Lond.). London: Baillière, Tindall and Cox, 1933. Pp. vii plus 341, with 16 plates. Price, 12s. 6d.

This small volume has the appearance of a modern novel, being bound and printed in a similar form and it is also of approximately the same length.

The subject of the book 'chronic indigestion' is such a wide one and as the symptoms appear in practically every disease of the stomach a more accurate title would be 'diseases of the stomach'. It is a useful résumé of stomach diseases and quite up to date and as such might be read with profit by any general practitioner, but it hardly appears worth the 12s. 6d. asked for it especially as the information provided will all be found in any recent edition of a standard book on general medicine. There are several good x-ray plates showing bismuth meal appearances in certain conditions.

Numerous references are scattered throughout the book and a long bibliography is appended. This will be no doubt of value to a reader in close touch with large libraries, but a book of this type will probably not appeal to such a man, whereas to the isolated

practitioner who is a much more likely purchaser these references can only be irritating as he is unable to consult the papers and books cited. Their only advantage can be that they show the author has taken considerable pains in presenting his subject as fairly as possible.

This book is one of the 'Minor Monograph Series' of which eleven volumes altogether have now been issued. Several of the leading publishing houses of medical books in England are at present issuing similar series of small books. It is difficult to imagine how purchasers of books of this type can be found in the present period of enforced economy, for none of them can be looked on as necessities as they only deal with limited aspects of medical or surgical subjects which are fully dealt with in the larger books.

P. A. M.

CARDIOVASCULAR PAIN AS A BIOCHEMICAL PROBLEM.—By Gordon Lambert, B.A., M.D., B.C. (Cantab.). London: H. K. Lewis and Co., Ltd., 1933. Pp. xi plus 75, with 23 illustrations. Price, 6s.

Dr. LAMBERT's interesting and illuminating monograph dealing with the causation of angina pectoris should be regarded as a real advance in the field of cardiology, in as much as it extends a new and interesting line of research to the biochemist for finding, if possible, a biochemical solution of the problem as to the causes of cardiovascular pain. The author has collected a large number of facts in proof of his statement that the causes of cardiovascular pain cannot be wholly explained by the findings of the post-mortem examination alone, whether macroscopic or microscopic. The pathological lesions found in association with angina pectoris are found to be very variable, cases having been recorded with no recognizable lesions in the heart, aorta or the coronary arteries; on the other hand, any or all these lesions may be present without the concurrence of anginal pain.

The author seems to be of opinion that there should be a common fundamental factor which would afford a common explanation to the causes of cardiovascular pain occurring in all ages, in all degrees of severity and in all types of lesions, and even in those cases in which no demonstrable lesions could be accounted for. After carefully discussing the commonly accepted beliefs based upon hypothesis, anatomical, physiological and pathological, the author seems to think that these do not rest on secure foundations and presents the view to his readers that there must be a unity, a common link, in all forms of cardiovascular pain. According to him, this may be found in the abnormal or 'toxic' contents of the blood stream supplying the myocardium—probably the products of an abnormal metabolism. We certainly agree with the author that we have to look to the biochemist for aid in the solution of the problem of arterio-sclerosis with which the anginal pain is so closely bound up, but we hesitate to go as far as the author when he says that the 'key' to the whole problem of both cardiovascular degeneration and cardiovascular pain will be found by the biochemist who will unlock the door for both the pathologist and the physician.

J. P. B.

RADIOLOGIC MAXIMS.—By Harold Swanberg, B.Sc., M.D., F.A.C.P. Quincy, Illinois, U. S. A.: Radiological Review Publishing Co., 1932. Pp. 126. Price, \$1.50.

This is a little volume of trite sayings collected from a page devoted to this subject in the *Radiological Review* for the last six years, coupled with short statements on radiological subjects contributed by prominent physicians who are not radiologists.

It is essentially a book for the general practitioner and aims at informing him of what the radiologist can do to help him in the various departments of medicine and surgery. It is by no means a textbook of x-rays; as far as it goes it should be of considerable assistance

to the busy practitioner. There is necessarily a fair amount of repetition in the text, but this does not detract from its value as a reminder when the radiologist may be useful.

Although as a literary effort the work cannot be regarded as worthy of the highest praise it should serve a useful purpose. It is certainly worth the modest cost involved.

J. A. S.

WHITLA'S PHARMACY MATERIA MEDICA AND THERAPEUTICS.—Revised by J. A. Gunn, M.A., M.D., D.Sc., F.R.C.P. Twelfth Edition. London: Baillière, Tindall and Cox, Ltd., 1933. Pp. xii plus 645, with 16 figures. Price, 12s. 6d.

THIS well-known book needs little recommendation as it has been the daily companion of hundreds of English-speaking medical men for the last three decades.

The publication of the new British Pharmacopœia has rendered this new edition necessary and it is very welcome as its forerunner the eleventh edition appeared eleven years ago. It is with regret that we note its author Sir William Whitla was unable to edit this edition himself on account of advancing years, but the volume has not suffered at the hands of the three authorities on pharmacology to whom he has handed it over, and it may still be recommended as one of the best if not the best book for the practitioner who does his own dispensing to have always within reach.

AIDS TO PATHOLOGY.—By H. Campbell, M.D., F.R.C.P. Sixth Edition. London: Baillière, Tindall and Cox, 1933. Pp. viii plus 252. Illustrated. Price, 4s. 6d.

THE sixth edition of this useful 'cram' book on pathology has now appeared. Many parts of the book have been entirely re-written, much new matter introduced, and the book brought up to date. It is clear, concise and contains a remarkably large amount of information in an accessible form. It will prove useful to the student requiring a hurried revision of the subject.

C. L. P.

SIMPLE INSTRUCTIONS FOR DIABETIC PATIENTS.—By Dorothy C. Hare, M.D., M.R.C.P. London: H. K. Lewis and Co., Ltd., 1933. Pp. 24. Price, 1s.

THIS little book is primarily meant to be of use as a guide to patients and nurses. It contains information

of somewhat broad and general interest, such as general hygiene, exercise, dieting, and the use of insulin, and as such may prove to be of value to diabetic patients undergoing treatment, as well as to nurses having to deal with such cases.

J. P. B.

PIERSOL'S NORMAL HISTOLOGY WITH SPECIAL REFERENCE TO THE STRUCTURE OF THE HUMAN BODY.—Edited by William H. F. Addison. Fifteenth Edition. Philadelphia and London: J. B. Lippincott and Co., 1932. Pp. x plus 478, with 435 illustrations, 43 of which are in colour. [Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta.] Price, Rs. 18-12.

THE fifteenth edition of this very useful book has undergone thorough revision, but has preserved all the characteristic features and size of its predecessor. The sections on nerve endings, glands, and biliary passages, the epithelium of the male urethra and the cyclic changes in the endometrium have been re-written, and a number of new figures have been added. Additional references have been added to the list of selected references given at end of the book.

The information contained in the book, so far as human anatomy is concerned, is very complete and the illustrations are admirable, carefully chosen and beautifully reproduced. We have no hesitation in recommending this book to all students of medicine.

C. L. P.

INTERNATIONAL HEALTH YEAR-BOOK, 1933. Volume VI. Geneva: League of Nations.

THIS volume does not lend itself to review because by far the greater part of the book consists of statistical tables, and many of the countries contributing reports give no more than these.

The fact that the contents refer to health matters as they existed in 1929, and are only available to the public at the beginning of 1933, makes the book of small immediate value. But as a book of reference in a concise form it will be of great use to all public health authorities and should be in all libraries dealing with health matters. The statistics compiled by all the countries contributing to it have been calculated on a uniform basis, so the book is of special value, as the figures for one country are directly comparable with those of any other.

Annual Reports

ABSTRACT FROM THE CENSUS REPORT OF BENGAL, 1931. BY A. E. PORTER, M.A. (OXON.), I.C.S.

Increase of population and birth control

THE population of Bengal in this Census is 51,087,338 and equations for total populations suggest a population of between 53 and 53½ millions in 1941. The prospect or even the possibility of so considerable an increase in a population already one of the densest in the world may lead to apprehension that the population of Bengal is rapidly approaching numbers which cannot be sustained at any reasonable standard of living upon the means of subsistence which Bengal can produce for long. If population actually does increase according to some such law as that illustrated by the logistic curve the fact that considerable increases are inevitable makes the apprehension futile. Pearl himself has pointed out that this inevitable increase need not necessarily increase the misery in the world since first this result has not happened up to the present, secondly—

'the orderly evolution of human knowledge justifies us in assuming that science will keep pace in discovering

means of expanding opportunities of happy human subsistence', and thirdly the human organism is itself adaptable to an extent not yet imagined. It cannot be denied that a large part of the population of Bengal lives at a very low level of subsistence, and that any increase of population must lead to increased distress unless the potentialities of the province are developed. What is suggested here is that these potentialities are such that pessimism as to the future condition of its population if considerable increases take place is not necessarily justified. Like the rest of India Bengal is notable for its undeveloped resources and the inefficiency with which such resources as it has are exploited. The soil is probably unlikely to deteriorate further and the general opinion about areas such as Bengal, where scanty manuring necessitates small crops, is that a dead level of yield was reached long ago and is conditioned by the rate at which plant food constituents are made available by weathering. The cultivator in Bengal practically never enriches the soil with any manure and the use of manures together with an improvement in the implements of agriculture which would then be rendered possible would probably increase enormously

the output of the soil. It has been estimated that improved methods would result in a reasonable expectation of increased food output of 30 per cent throughout the whole of India. There is no doubt that any additional labour required under a more intensive form of cultivation could easily be obtained since the agriculturist in Bengal on the whole probably works less than agriculturists in almost any other part of the world, also of the total area cultivable only 67 per cent is now actually under cultivation. If the total cultivable area were brought under cultivation and if improved methods of cultivation yielding an increase of 30 per cent over the present yield were adopted it is clear from a simple rule of three calculation that Bengal could support at its present standard of living a population very nearly twice as large as that recorded in 1931. Fresh areas in course of time will be brought under cultivation as lands on the Bay of Bengal accrete and reach a stage suitable for cultivation. Even at present it is clear that by far the majority of the food-stuffs consumed in Bengal are locally produced. During 1930-1931, taking only grains, pulses and flour, salt, sugar and spices, provisions and oilman's stores Bengal imported goods of the value of Rs. 821 lakhs and exported goods of the value of Rs. 281 lakhs. But the balance of trade during the same year amounted to Rs. 34,52.41 lakhs or more than three times the aggregate export and import trade. The sea-borne trade of Calcutta is not confined to goods originating in or meant exclusively for Bengal, but in the year 1930-1931 jute, tea and hides contributed 77½ per cent of the total and Bengal contributed all the jute, nearly all the hides and a very considerable part of the tea. It is consequently clear that the favourable balance of trade to a very small extent only was dissipated outside Bengal and that the balance itself provides sufficiently for an enormously increased importation of food-stuffs were it necessary to import them at any time. Not only agriculture but also industry is at present in Bengal practically in its infancy. Reviewing production in India a Bengali writer in 1924 came to the conclusion that the— 'outstanding feature of the productive system of India is its inefficiency which is shown by the great wastage of resources on the one hand and the lower productivity of the industries on the other It is insufficient production to which is due India's poverty, both absolute and relative The lack of capital is partly responsible for the present low productivity but could not be regarded as the fundamental cause of insufficient production in India Insufficient production is the result of inefficient labour, i.e., lack of capacity on the part of the people to mobilize the physical, intellectual and moral forces of the country and to organize land and capital effectively for national production'. Improvement in methods of production both agricultural and industrial should, therefore, very easily make possible the subsistence of such an increased population as is suggested by the figures already discussed and the considerations deduced in this paragraph also make it possible to hope that such an increase of population may be attended with a very considerable increase in the material condition of the people and in the standard of living. It is clear at least that it is not yet time to indulge in gloomy forebodings on the grounds that Bengal is over-populated, provided full use is made of the available resources of the country by improved methods.

A final problem suggested by the growth of population in Bengal concerns the enormous wastage of life with which that growth is achieved. It is clear that what is of importance in population growth is the rate of increment. A high rate of increment can be achieved by a relatively low birth rate if the death rate is also low, whilst on the contrary a comparatively low rate of increase results from even a high birth rate if the death rate also is high. Actually both the birth rate and the death rate in Bengal are very high and there is consequently an appalling wastage of reproductive energy in

maintaining the present increase of population. If the logistic theory of population growth is correct a retarded rate of increase is inevitable at the upper stages of the cycle of growth until finally a population is reached which to all intents and purposes is stationary. France in Europe where there is a notoriously low birth rate probably illustrates this position best but an exhaustive enquiry into the Arab population of Algiers suggested to Pearl that the retardation of the rate of increase is in general effected at the upper stages of the population growth by decrease both in the birth rate and in the death rate. The Arab population of Algiers showed both a decrease in the birth rate which could not be ascribed to any voluntary measures and a decrease in the death rate which equally could not be ascribed to improvement in public health measures since the traditional customs of the Arabs offer the utmost possible resistance to any changes in their habits which would improve sanitary conditions. Attempts to effect a retardation of the rate of increase by voluntary limitation of the birth rate are almost certainly doomed to failure particularly in Bengal. They are repugnant to common sentiment in this country, the methods adopted are so expensive as to be beyond the reach of the great majority of the inhabitants and it is probably true to say that there are as yet none which can be relied upon as being absolutely certain and satisfactory. Figures for the different strata of society show that there is no evidence that contraceptive measures are used by the upper classes or those engaged in professions and the liberal arts; and it is certain that they are not practised at all in the lower strata of society. What appears to happen, if the analogy of Western Europe may be accepted, is that a decrease in the birth rate is inevitably followed at some period by a corresponding decrease in the death rate. It is clear also that fertility in western countries decreases with the increase of wealth and intellectual interests. It is therefore possible to expect that a reduction of the birth rate by the adoption of improved measures of public health accompanied by an improvement in the standard of living, an increase in the spread of education and perhaps principally by a further emancipation of women and their introduction to spheres of usefulness and activity from which they are now in Bengal generally debarred by social custom and by the institution of purdah will in due course result in a decrease in the birth rate corresponding with the decrease in the death rate which it is the object of public health measures to bring about.

ABSTRACT OF THE REPORT OF THE GOVERNMENT OF MADRAS, LOCAL SELF-GOVERNMENT DEPARTMENT (PUBLIC HEALTH). (CIVIL HOSPITALS AND DISPENSARIES—TRIENNIAL REPORT—1929-31)

THE following brief abstracts from this report will show that Madras, always one of the most progressive sections of India regarding medical education and the care of its sick, is still advancing although severely hampered by the universal economic difficulties of the present time.

One of the chief features of recent medical development has been the opening of an increasing number of rural dispensaries, to the medical officer in charge of which Government gives a subsidy in proportion to his qualifications and a further subsidy for a midwife. Sometimes these subsidies are added to by the taluk boards who control these dispensaries. At the close of the last triennium there were 326 of these subsidized dispensaries; at the end of the present triennium there were 506 in operation.

Medical education has improved considerably in the medical colleges, while the bigger medical schools have benefited by the closure of the less important schools and the concentration of teaching talent in the larger centres. The medical schools, however, require a considerable further improvement before we can be satisfied

that we are giving the best possible teaching with the means at our disposal.

Several minor improvements in the licentiate course have been carried out and others are still under the consideration of Government. The more important of the latter are those to raise the examination standard and to extend the L.M.P. course to five years.

Medical inspection of schools.—The Government requested the Surgeon-General to formulate an experimental scheme for introduction in two districts.

On a rough calculation, the routine inspection of school children in the two districts suggested was estimated to cost Rs. 56,000 a year. The Government observed that the extension of a scheme of this kind to the whole Presidency would involve an annual expenditure of many lakhs. While the Government do not underrate the importance of medical inspection in schools they were constrained to observe that the present scheme is far beyond anything that the provincial finances can afford. The Director of Public Instruction was therefore requested to work out in consultation with the Surgeon-General a less expensive scheme which it would be possible to introduce in selected areas in the first instance and which would be capable of expansion as funds permit.

The total number of medical institutions of all classes working in the Presidency at the beginning of the triennium under report, i.e., on 1st January, 1929, was 1,089 and 1,245 at the end of 1931, i.e., 1,005 in rural areas and 240 in urban areas. There were thus 156 institutions more at the end than at the beginning of the triennium. The increase is due to the opening of additional subsidized rural dispensaries.

In 1929 Doctor Santra of the British Empire Leprosy Relief Association, Indian Council, New Delhi, carried out leprosy survey work in the districts of South Arcot and East Godavari in this Presidency and opened leprosy clinics in those districts. The survey had the effect of stimulating the interest of district boards and six of them have appointed leprosy officers in their respective districts.

The actual number of lepers in the Madras Presidency has been estimated in various ways and with a considerable difference in the totals arrived at. Thus

1921 Census	16,595
1931 Census	33,069
Health Department investigation in 1930	48,000
Rough expert estimate	100,000

Doubtless one reason for the apparent increase in the number of lepers is that owing to propaganda and evidence from the leprosy clinics that the disease is not hopeless, but can usually be arrested when the patients come early, the patients are now coming forward more readily instead of endeavouring to conceal their disease.

Midwifery.—The total number of labour cases conducted in all classes of medical institutions during 1931 was 140,403 normal and 15,003 abnormal. This branch of activity has more than doubled in the last six years.

Radium.—Radium has been used increasingly by the surgeons attached to the large hospitals in Madras and Vizagapatam, and is found to be of the greatest value. Government now possesses over 600 milligrammes of radium of an approximate value of Rs. 1½ lakhs.

Honorary medical officers.—The scheme of appointing honorary medical officers to all district headquarters and government hospitals in the mofussil was introduced in 1929 and several officers were appointed. The scheme has made considerable progress as many private medical practitioners with special attainments in the branches of medicine and surgery were appointed as honorary medical officers in the city state hospitals as well as in the mofussil.

At the beginning of 1929 there were only 9 honorary medical officers working in government hospitals and at the end of the triennium there were 90 and the number is still increasing.

It has been calculated that without our existing staff we should, to deal with the same amount of work, have

to employ more medical staff at a cost of Rs. 1,85,000 per annum and the honorary staff may therefore be considered to be saving Government this amount annually.

During the last year of the preceding triennium was formed the Madras Nurses and Midwives Council to establish a register of trained nurses and midwives and to supervise the standards of education in these occupations. The council has now on its registers 618 nurses, 1,353 midwives and 6 dhais. The Nurses and Midwives Council has also arranged reciprocity of recognition as regards qualifications with the General Nursing Council for England and Wales and the Joint Nursing and Midwives Council of Northern Ireland. The registration performed by this council is believed to be the only registration of nurses and midwives so far in India under an Act of the Legislature.

ABSTRACT OF THE ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR AND ORISSA FOR THE YEAR 1931

The use of bacteriophage

THE districts of Muzaffarpur and Purnea were selected for the experiment for the following reasons:—

(1) Because they are regarded as the worst cholera districts in their respective divisions of Tirhut and Bhagalpur.

(2) Each of these districts has a well-organized health staff through whom it was proposed to distribute bacteriophage, both for preventive and curative purposes, and to obtain fairly accurate data regarding the case incidence and mortality from cholera.

(3) The two districts are relatively well provided with roads, except in one section of Purnea, which render most villages in the district fairly easily accessible.

During the whole course of the experiments, no inoculations were carried out in either district, and no disinfectants were used. Essential-oil mixtures for the treatment of cases were not permitted, and as far as possible bacteriophage alone was used for the treatment of cases.

The experiment brought out many interesting facts some of which are:—

(1) It was definitely established that the duration of an epidemic was considerably shortened when bacteriophage was used. Thus the average duration of a cholera epidemic in a thana area where the usual methods of dealing with an outbreak are employed has been estimated as 83 days. In these two districts where bacteriophage was used the epidemic subsided completely in 14 days. Similarly, in villages the average duration of an epidemic has been estimated as 23 where the usual methods are employed, whereas it only lasted 3 days in villages in these two districts where bacteriophage was used.

(2) Although cholera was not as severe as usual in 1931, the mortality from cholera in these two districts was not only the lowest amongst the districts in their respective divisions, but the lowest in the whole of North Bihar.

(3) Financially there was a considerable saving of money to the two district boards, as no disinfectants, and no other remedies for the treatment of cholera were purchased. Government was also saved the cost of cholera vaccine which would otherwise have had to be supplied to the districts.

(4) Bacteriophage is tasteless, colourless, and odourless, and not only was the treatment of wells with it not objected to, but the villagers actually asked for it when they had once had it in their wells—a very different story to what happens when an attempt is made to chlorinate wells.

Unfortunately no very spectacular result was obtained during the year under report with bacteriophage. It was a mild cholera year and although other districts in North Bihar reported more attacks and deaths than

these two districts, their figures were also lower than usual. A conclusive verdict in favour of its adoption throughout the province has been deferred, and the experiment is being continued in the same two districts in 1932.

The sale of quinine treatments at the various post offices in the province has been in force for many years. The sale during 1931 amounted to a total of 536.4 pounds of quinine sulphate as compared with 501.2 pounds in the previous year.

At Puri the year under review was of special interest as the Nabakalebar ceremony had to be performed during the Rath Jatra. The ceremony, which consists in the complete renovation of the wooden figures representing the three deities in the temple of Jagannath, is performed at long intervals, generally about 18 years. The last ceremony of the kind took place in 1912. Pilgrims to Puri in these years acquire special merit, and the attendance in these years is usually more than double that of an ordinary year. In 1912 the total number of pilgrims estimated to have visited Puri was about 250,000 but no details of these figures are given. It is not easy to arrive at the figures for 1931 but 161,550 is considered to be a fairly accurate estimate.

To prevent a recurrence of what happened at Puri after this ceremony in 1912, when no less than 1,053 deaths were recorded in the town itself, and the serious epidemic which followed in the Puri and neighbouring districts, special measures were taken by the public health department, the municipality, the district board and the Bengal Nagpur Railway authorities.

Government sanctioned the employment of a special temporary staff of doctors for the supervision of the sanitation in the town, for inoculation in the town and at the railway station at Puri, and for inoculation duty at Cuttack and Balasore. The municipality engaged an extra staff of sweepers for the sanitation of the town. The district board established inoculation centres along the roads traversed by pilgrims from the district, and the railway authorities arranged for the inspection of pilgrims travelling by rail at the important junction stations, established eight disinfecting stations between Kharagpur and Puri, and provided sheds for camps and camp hospitals at certain stations where hospital accommodation did not exist.

The engineering branch of the public health department installed six engine-driven pumps with connected tanks and taps at six of the more important wells, and ten hand pumps at other wells, and the municipality arranged for hand pumps at sixteen other wells and sank 31 small tube wells.

Except in wards 4 and 5 of the town, where bacteriophage was used, the whole of the remaining wells were chlorinated throughout the *mela* period.

Inoculations with cholera vaccine were commenced in April in the town of Puri amongst the permanent residents, and as the immunity conferred by these early inoculations persisted through the *mela* period these figures are included in the totals given below. The figures however for the district are only those done amongst definite pilgrims to Puri for the Rath Jatra—

Total number of inoculations done in the town	34,226
Total number of inoculations done in the district	43,249
TOTAL	77,475

In addition to these figures a total of 6,643 inoculations were carried out in the Cuttack and Balasore districts amongst pilgrims proceeding to Puri, so that the total number of inoculations carried out in the province in connection with this festival was 84,120. This does not include the number inoculated by the public health department of Bengal.

An attempt was first made to protect pilgrims attending Puri for the Snan Jatra and Rath Jatra in

1927 and the following figures are of interest as they illustrate the steady progress that has been made with this important preventive measure. These figures are only for the town itself, and for a short period immediately preceding the Snan Jatra and following the Rath Jatra.

Year	Number of inoculations
1927	7,937
1928	16,869
1929	32,155
1930	42,047
1931	34,226

The figure for the town in 1931 would have been still higher, if the district board arrangements for the inoculation of pilgrims travelling by road had not been so complete.

There was no little anxiety in the public health department during the course of the *mela*. Cholera was prevalent in all the districts of Orissa, more especially in the district of Puri itself, and cases of cholera were actually occurring in Puri town at the time. But the elaborate precautions taken, and the thorough arrangements made were entirely successful as the following figures show. There were only 73 cases of cholera in the town during the *mela*, i.e., up to 31st July, and only 9 deaths as against 1,053 deaths in 1912.

ABSTRACT OF THE ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1931

A TOTAL of 5,523 deaths from cholera were reported from Assam in 1931, as compared with 6,332 in 1930. The death rate per mille of population for the year 1931 was 0.70 as compared with 0.92 in 1930 and 1.53 the decennial average. The decrease in the incidence of cholera and smallpox in 1931 as compared with that in 1930 and the decennial average is partly due to the limitation of movements of individuals resulting from financial stringency.

During the year a provincial malaria committee was constituted with the Inspector-General of Civil Hospitals as president, the principal, Ross Institute, the research officer, Assam Medical Research Society, Director of Public Health, secretary to the Government of Assam in the transferred departments and the secretary, Assam Medical Research Society, as secretary to consider and advise Government on all malaria schemes. The object in forming the committee is to obtain co-ordination between various authorities interested in the malaria problem in the province. Malaria is endemic in Assam and it is hoped that the problem will be successfully tackled by the co-operation of the parties concerned.

The number of deaths from kala-azar rose slightly by 64 from 953 in 1930, to 1,017 in 1931. The Kamrup, Darrang and Goalpara districts contributed to the increase. The increase which is insignificant does not require any explanation. The number of patients treated fell from 16,430 in 1930 to 9,759 in 1931. The method of diagnosis of kala-azar adopted was as usual by the formolgel test and by clinical signs and symptoms. Treatment throughout the province is by means of intravenous injections with urea-stibamine. This treatment is wholesale and free. A limited experiment with neostibosan is being undertaken in the Kamrup district. Special attention is being paid to intensive and detailed surveys in order to detect fresh cases. Villages within a certain radius of dispensaries in kala-azar-infected districts are surveyed by the medical officers in charge. Sub-assistant surgeons are specially deputed to survey other areas where a recrudescence of the disease is suspected. In Cachar all suspected villages in the Hailakandi subdivision were surveyed during the year and all cases detected were brought under treatment. On account of a marked decline in the number of cases, the special kala-azar indoor wards at

Habiganj, Sunamganj and Sylhet sadar hospitals were closed during the year. Three outdoor dispensaries in this district were closed as they were no longer necessary and one was opened. Intensive surveys were undertaken in different parts of the Goalpara district, resulting in the necessity for opening three new out-centres. Intensive surveys were carried out in the Kamrup district and this resulted in the necessity for opening two new dispensaries and four out-centres. Four kala-azar dispensaries had to be closed. The indoor kala-azar wards attached to the Gauhati and Barpeta hospitals were transferred to the Medical Department as the necessity for their retention ceased to exist. Two kala-azar dispensaries in the Nowgong district and three in Sibsagar district were closed owing to the reduction in the number of kala-azar cases in those districts. The Garo Hills district was surveyed for kala-azar cases by four hill-men sub-assistant surgeons as in the previous year. During the year the number of beds in the Tura kala-azar hospital was reduced from 200 to 100 owing to the fall in the number of patients.

During 1931, 5,895 deaths from respiratory diseases were returned, as compared with 5,859 in 1930.

A campaign against yaws was started in January 1931 in the Digarukhetri area by the civil surgeon of the Kamrup district. The disease was first detected in 1929 in this area by Dr. Nepal Chandra De of the kala-azar department. The ravages of the disease were responsible for much suffering and mutilation amongst the Mikirs and Lalungs who inhabit this area. The benefits of treatment were soon realized and the people came forward in increasingly large numbers. A total of 735 cases were treated at Digaru, Kapalkata, Khetri and Verakuehi. To the west of these dispensaries, cases were found amongst Rabhas, Kacharis and Khasis inhabiting the submontane region around Boko. At the local board dispensary at Boko, 66 cases were treated and a few also at the Hahim kala-azar dispensary. A large number of drugs were given a clinical trial, first supplies in most instances being obtained free through the courtesy of the manufacturers. An endeavour has been made to standardize a satisfactory course of treatment. The question is one of obvious importance in view of the widespread distribution of this disease throughout Assam. The results are not yet complete. The civil surgeon, Kamrup, believes that well-established yaws is as resistant to cure as syphilis and has to be treated with corresponding thoroughness.

ABSTRACT OF THE ADMINISTRATION REPORT OF THE DIRECTOR OF MEDICAL AND SANITARY SERVICES, CEYLON, FOR 1931

THE hookworm campaign begun fifteen years ago is still being vigorously prosecuted but 79 per cent of the total population of the island is still infected.

Reorganization of the units engaged in this work has resulted in a saving of over Rs. 80,000 but in spite of this the number of treatments given was greater than during the previous two years and the third highest that has ever been given in a single year.

The actual number treated was 1,406,406 and one death is recorded. This was in a child aged ten years*

* (Note.—As the routine dose for children of this age is 9 minims, according to the 1930 report, it seems possible that the child referred to above may have presented certain contra-indications and have been given a reduced dose accordingly. Therefore the fault in this case appears to have been rather in giving the dose to an unsuitable case than that the drug exhibited a surprising and unusual effect in a healthy person. The latter is the usual excuse advanced for deaths from anthelmintic drugs but, in our opinion, if the real facts could be elicited in deaths of this kind, it would be found very frequently that the victims were suffering from some condition that a brief clinical examination would have revealed and the existence of which should have exempted the particular individual from treatment on that occasion.—EDITOR, I. M. G.)

who received a dose of 5 minims of oil of chenopodium and died 76 hours afterwards. Up to the age of ten years oil of chenopodium alone is given and all persons over the age of ten receive a mixture of carbon tetrachloride and oil of chenopodium graduated according to age. The maximum dose employed in adults is 30 minims of carbon tetrachloride and 10 minims of oil of chenopodium. This is somewhat less of both drugs than is usually employed but as it appears to be fairly efficient and safe there is nothing to criticize in this.

A preliminary investigation of hexylresorcinol is reported; 52 hookworm cases with 21 per cent cures, and 45 ascaris cases with 49 per cent cures are recorded.

As the test of cure appears to have been a negative result using Stoll's dilution technique the cure rate is probably much higher than if Lane's centrifuge had been employed. The drug is said to have been supplied by the Rockefeller Foundation and so one of the great objections to it, viz, the price, is not appreciated by the Ceylon authorities. If the drug had been purchased and the recommended dose of 1 gramme given to each of the patients treated the cost of this small investigation for the drug alone would have been between 60 and 70 rupees.

TRIENNIAL REPORT ON THE WORKING OF THE HOSPITALS AND DISPENSARIES IN BIHAR AND ORISSA, FOR THE YEARS 1929, 1930 AND 1931

THE following abstracts from this report are applicable to other provinces besides the one in which they have been written, for a similar state of affairs exists in many parts of India.

Hospitals and hospital maintenance.—The principle followed has been that medical relief should be not only a charge on public funds but that it should be also managed by public officials, be they State or otherwise. This principle was inevitable from the inception of medical relief in this country and the people have never been educated to expect that this method is other than the only one that is applicable or necessary for the province.

But there is every reason to suppose that when local bodies instituted a subscription list in their hospitals and dispensaries, that after the initial outlay of expenditure in constructing and equipping such institutions, it was expected that the people in the locality should help to support these institutions, not only for their own benefit but for the benefit of the districts and country at large.

The entirely self-supporting dispensary maintained by public charity similar to the cottage hospital in England was perhaps the object of instituting subscription lists and managing committees, but if so, the dream has not materialized. The only institutions that are really charitable institutions in the province are class V dispensaries maintained entirely at the expense of some public-spirited gentlemen who have a commendable consciousness of civic responsibility.

With the twofold intention of preventing abuse of hospitals and obtaining monetary local assistance, the institution of a small fee for well-to-do patients was recommended for the consideration of the district boards in 1927. The response to this appeal throughout the province up to very recently was of a negative nature.

Local support therefore to any dispensary or hospital as regards maintenance can be ruled out as non-existent and the onus of upkeep is dependent on public funds. If we admit as we must admit for this province that medical relief is a charge on public funds, we must recognize that the people themselves are apathetic in contributing to any institution where it is believed and acted upon, that any needs of the institution will be met from public funds. This apathy is comprehensible and until the impression is created that the time has arrived for the charitable instincts of the people to be guided into this deserving channel, further progress will be difficult. That the people themselves are not

uncharitable is obvious from everyday observation, but that they should contribute to an institution which is being maintained by public funds is another matter, and the imposition of a small fee which has been advocated and commenced in some institutions in this province may be viewed from the angle of educating the people to the needs of the sick poor, as much as that it should be considered as a competent source to diminishing the burden of maintenance charges.

There is another important point to be considered in this connection, *viz.*, the ever-growing number of medical men turned out from the schools and colleges who have to earn a livelihood; in those localities where free treatment is obtained from the hospitals the imposition of a fee on the well-to-do patients will assist these struggling practitioners.

Medical personnel.—At present the medical relief of the remoter parts of the district falls upon the hospitals and dispensaries in charge of doctors of the licentiate class. These doctors have qualified from the medical schools in this province generally and to a smaller extent from the Bengal Province, but the latter are gradually being replaced by the licentiates of the schools of this province.

One must record however that the standard of efficiency of the doctor in charge of local fund dispensaries is below what it should be. I am taking the cadre as an average and fully recognize that there are brilliant exceptions but my experience of the average licentiate in the employment of district boards is that they are not good examples as disciples or exhibitors of the advantages of a scientific training in medicine.

The main causes of this state of affairs are twofold, one dependent on the standard of training received at the medical schools which will be discussed later, and the other on the inherent defects in the doctor himself. The average L.M.P. in district board employ is cast on his own resources in outlying and isolated dispensaries and neither opens a medical book nor has any ambition to do so. This may appear to be strong indictment against the professional capacity of the licentiates, but even if it is overstated it is important in the present times owing to the tendency of the district boards to build dispensaries in which medical officers are appointed who are disciples of one of the indigenous medical systems.

It was stated in the last triennial report that 'western medicine at its best has nothing to fear from a comparison with the indigenous systems of medicine', but the qualification 'at its best' tends to confuse the issue, and in general medical relief in the province we are not concerned so much with the exceptions but with the average; and if our policy is that medical relief should be in the hands of the people best qualified to give that relief we should periodically take stock of the standards of qualification.

The standard of efficiency of the medical officer is intimately related to the policy now advocated of charging fees at hospitals and dispensaries.

Nursing.—Most of the hospitals are without any nursing arrangements. Their limited funds cannot afford to pay for Anglo-Indian nurses while Indian nurses are not easily available owing to the absence of training centres and of a suitable syllabus for training.

Medical education.—The difficulty of newly-qualified practitioners in finding employment is already becoming acute; the number of applications received for vacancies in Government service is an indication of the trend of events and it is a matter for consideration as to the extent the administration is concerned with the overcrowding of the profession.

This statement of overcrowding requires examination. If counting heads was the only consideration then the proportion of medical men to population is not excessive and no overcrowding is apparent.

But whereas in a country like England the proportion of medical men to population may be placed in round figures at one in 1,000 yet such a comparison is useless for this country. The mass of the people live in

villages and the average wealth of the occupants is not such as to guarantee a living wage to any qualified medical officer settling down in such a community; the result is that the medical practitioners are compelled to flock to the larger towns and it is in these large towns that the evidence of overcrowding is so apparent.

This overcrowding is without doubt leading to a lower ethical standard amongst medical practitioners and although this may be considered as inevitable, the administration will be forced eventually to face this question and as it is a difficult one, not to dodge it, but to overcome it. The position as I see it is as follows:—

(1) Young men are being educated in larger numbers every year and it is inevitable therefore that a large proportion of these masses will join the medical profession as one of the outlets for an educated man.

(2) The limitation of entries into the medical schools or colleges of the province will not solve the problem so long as the medical men from other provinces are allowed to settle down here and practise with only the medical registration fee to pay.

(3) The protection of the qualified man from quacks, charlatans and other species of that ilk that infest both large towns and the country villages is a matter which however should receive careful consideration and is one which not only affects the qualified medical practitioners but the general public also. Just as the agitation has commenced to protect the public in this country from quack medicines, so it is time for agitation to commence on the *bona fides* of not only the ammunition but the gun that fires the ammunition, and the latter is of greater importance.

(4) The steady increase in the numbers of lady doctors which will inevitably take place further complicates this question and is one that will affect this country with its customs and prejudices much more than other countries.

The importance of raising the standard of the sub-assistant surgeon is intimately related to what has been said with regard to overcrowding of the medical profession.

If graduates are finding a difficulty in obtaining employment after qualification, it is not difficult to visualize that in the future the out-patient dispensary may receive some of the surplus stock of these graduates at the expense of the licentiates. The course of events will follow the laws of supply and demand and when the supply exceeds the demand, the price of the commodity will be lowered, and the district boards and local bodies will naturally prefer to obtain the services of a cheap but efficient assistant surgeon rather than a cheap but mediocre licentiate, and this obviously will be to the benefit of all concerned.

What then is to be the position of the licentiate? Is that body of very useful citizens who were the pioneers of scientific medicine in this country to be crowded out by a better qualified man, or is that cadre to be raised from its present standard to a position where it can still compete and hold its own with the average practitioner? We must take it for granted that the first recommendation to be made to raise the standard of the licentiate will be to prolong the curriculum by another year to five years, which will bring it into line with the curriculum required by graduates but will *ipso facto* increase the cost of training. The fact that at present the poorer classes can obtain a licentiate degree in allopathic medicine is one that is all important, and whereas want of funds may debar many deserving students from qualifying as graduates, this is perhaps subsidiary to the lack of the higher standard of preliminary education which is necessary for a graduate, and which higher standard the parents have not been able to afford. It would appear then that if riches are not to impede the aspirations of the poor student in obtaining a qualification in allopathic medicine the obligation to maintain the licentiate is a real one; but as stated above there is on the other hand the obligation on the administration that if the

licentiate is to be retained he should be of such a standard of efficiency that he should be able to maintain the good name and repute of scientific medicine.

Moreover if it is admitted that qualification in the medical profession is not the end but the means to the end, and after qualification as the licentiate has equal opportunities with the graduate to make good, the policy of retaining the licentiate is justified.

ABSTRACTED FROM THE ANNUAL REPORT OF THE DIRECTOR, INSTITUTE FOR MEDICAL RESEARCH, FEDERATED MALAY STATES, FOR THE YEAR 1931. KUALA LUMPUR: PRINTED AT THE FEDERATED MALAY STATES' GOVERNMENT PRINTING OFFICE. 1932

The opening sentence of this report is typical of most publications of this nature that we are receiving just now, it reads as follows:—'The shrinkage in public funds consequent upon the present universal economic crisis has not been without influence on the activities of the Institute.'

But when we turn to the detailed record of the work done we cannot see where the Institute's activities could have been curtailed for if we take malaria alone it is difficult to imagine how a fuller year of work could have been carried out by a single institution. The work on malaria is so many-sided and the amount of information supplied is so great that on account of limitations of space only a small part of it can be abstracted; we have therefore confined our abstract to report on drug prophylaxis and therapeutics.

MALARIA Prophylaxis

An experiment on the prophylactic value of plasmoquine simplex when exhibited twice weekly in an adult dose of 0.04 grammes was completed. The venue of

improvement in the general physical condition of the labourers was very satisfactory, an observation which was confirmed by the sick rates. The total sick rate fell by 51 per cent on the experimental estate, by 11 per cent on one of the control estates, but rose by 21 per cent on the second control estate.

Quino-plasmoquine

In a malarious village near Kuala Lumpur there had been a number of cases of clinical malaria among the police force. Permanent anti-malarial work was out of the question, and it was suggested that quino-plasmoquine might be employed for its prophylactic effect. The police, including dependants, totalled 63, and, at an examination before the commencement of treatment, the spleen rate was found to be 10 per cent and the parasite rate 5 per cent. The dosage adopted was 2 tablets daily, i.e., 0.02 grammes of plasmoquine plus 0.6 grammes (9 grs.) of quinine. For the first week this preparation was taken daily, but on successive weeks it was taken on Mondays, Tuesdays and Wednesdays only.

Since the application, in October, of this form of prophylaxis there has been one case of sub-tertian malaria in a policeman who was parasite free at the time of the preliminary survey. There is doubt, however, if he had taken the drug regularly. An investigation of the urines, passed by the police, indicated that a number of the men were probably avoiding treatment.

THERAPEUTICS

During the year several drugs have been submitted to this Institute for testing in regard to efficacy in the treatment of malaria. Including control cases, 169 individuals have been specially treated and observation has been continued after the termination of treatment for periods varying from a few days to several months. The number of cases, together with the drug and daily dosage, are summarized in the following table:

DRUGS AND DAILY DOSAGE

Type of malaria	Quinine bihydrochloride gr. xx	Quinine bihydrochloride gr. xxx	Quinine bihydrochloride gr. vi	Quinine-stovarsol gr. xii	Malarcan 12 tablets	Atebrin ('Erion') 0.2 to 0.4 gm.
B.T. ..	10	14	6	13	1	13
S.T. ..	8	11	1	10	8	18
Q. ..	9	19	6	12	1	9
TOTALS ..	27	44	13	35	10	40

the experiment was a malarious rubber estate with a population of about 330. Two adjacent estates with populations of 405 and 362 served as controls, and quarterly surveys for parasite and spleen rates, hæmoglobin percentage, and anopheline breeding-places were undertaken on the three estates.

As regards sub-tertian malaria, the results, judged from the parasite rates, were somewhat inconclusive, but, towards the end of the experiment, no *P. falciparum* gametocyte carriers were found on the experimental estate. The method of prophylaxis was found to be less satisfactory for benign tertian malaria, and it was concluded that plasmoquine has, perhaps, a less definite gametocidal action on *P. vivax* than on *P. falciparum*.

On the other hand, the effect of the measure on the incidence of clinical malaria was definite. In the twelve months preceding the experiment, the sub-tertian and benign tertian cases totalled 30.4 and 52.5 per cent of the population on the experimental estate, i.e., a total of 82.9 per cent. Throughout the experimental period the incidence was 7.0 and 8.7 per cent for sub-tertian and benign tertian, i.e., a total incidence of 15.7 per cent only. The fall in the splenic index and the rise in the average hæmoglobin percentage were small, but the

Atebrin ('Erion')

A new preparation, which tentatively was given the name of 'erion' and is now to be known as 'atebrin', has recently been produced by the makers of plasmoquine.

The supply was received in the form of tablets. The drug is somewhat bitter to the taste and is fairly soluble in water to which it imparts a bright yellow colour. Unlike plasmoquine, but like quinine, it shows fluorescence under ultra-violet radiation.

The investigation of its properties is still proceeding.

Up to the present, 40 cases have now been treated with this new synthetic drug. It compares favourably with quinine on all counts except in the rate of destruction of the trophozoites of *P. falciparum*. The drug is not unpleasant to take and no marked toxic symptoms have yet been observed, though a temporary yellow discoloration of the skin and sclerotics sometimes occurs. The dosage employed was about one-seventh of that for quinine. According to the tables accompanying this portion of the report no relapses occurred in any of the three types of malaria treated with atebrin whereas there were 5/13, 3/15, 5/19 relapses in

control cases of benign tertian, malignant tertian and quartan respectively, which were treated with quinine.

Quinine-stovarsol

Work on this drug has been continued, and comparisons made with cases of sub-tertian, benign tertian, and quartan malaria, treated with quinine-stovarsol, 0.75 grammes (12 grains); quinine bihydrochloride, equivalent in dosage to that contained in the quinine-stovarsol, i.e., 0.37 grammes (6 grains); 20 grains of quinine bihydrochloride and 30 grains of quinine bihydrochloride daily.

The results of these treatments have been compared with reference to the rate of disappearance of parasites; the occurrence of relapses; the relief of symptoms; gametocidal properties; the reduction in the size of the spleen, and the increase in haemoglobin percentage and in the number of erythrocytes.

The general conclusions may be briefly stated as follows: The stovarsol contained in quinine-stovarsol has a definite parasitocidal effect on *P. vivax*. Twelve grains of quinine-stovarsol daily is as effective in benign tertian cases as 20 or 30 grains of quinine, but the former drug has the disadvantage of being less efficacious in quartan and sub-tertian malaria and is therefore of little use in apparent, or concealed, cases of mixed infections. Further hyperpyrexia and exacerbation of symptoms may occur during the first twenty-four hours of treatment in all three types of malaria infection. It is not superior to quinine in regard to the prevention of relapses, and is without action on sub-tertian gametocytes. One crescent carrier, after continuous treatment with quinine-stovarsol for 25 days, infected anopheline mosquitoes, and hence the drug can have little effect on the viability of the sub-tertian gametocyte. With these disadvantages there appears to be little place for quinine-stovarsol in tropical practice, particularly as the preparation is about five times more costly than quinine.

Malarcan

This preparation is said to have the formula methyl-acridine-methyl-cupreine-dehydrocholate; that is, a compound of a stereo-isomeric base of methyl-cupreine (quinine contains methyl-cupreine as part of its structural formula while the stereo-isomer of quinine is quinidine) combined with methyl-acridinium-chloride and dehydrocholic acid. Malarcan, in high dilutions, like quinine, shows fluorescence under ultra-violet light.

A supply was obtained sufficient for the treatment of ten cases, including one quartan, one benign tertian, and eight sub-tertian infections. Twelve tablets of malarcan were found to alleviate symptoms and to destroy parasites as effectively as quinine in a dosage of 30 grains. Cases were treated for from 7 to 14 days and subsequently kept under observation for periods ranging from one to six weeks. No relapses were observed. The effect on the gametocytes of *P. falciparum* was, however, negligible and, in view of the fact that the cost of malarcan is approximately six times that of quinine, it is unlikely that its use will become general.

Control cases treated with quinine

Quinine was exhibited to control cases in a daily dosage of 30 grains of the bihydrochloride, and certain points of interest have been noted from a close study of them. Quartan trophozoites and schizonts may persist in the peripheral blood for two days after the completion of seven days treatment. In similarly treated cases, quartan gametocytes were demonstrated in the peripheral blood five days after the cessation of the course.

Careful measurement has shown that in some cases the spleen becomes larger during the first two days of treatment, but subsequently, with the disappearance of parasites, its size diminishes. This initial enlargement may be due to the increased activity in destroying quinized parasites and damaged red cells.

Despite preliminary purgation, the absorption of quinine during the first three or four days of treatment appears sometimes to be irregular, if gauged by the quantity excreted in the urine. The disappearance of parasites from the peripheral blood is delayed in such cases.

When patients first came under observation, the parasites found in the peripheral blood may have been sub-tertian or quartan. But, after a relapse, benign tertian parasites only have not infrequently been found. Similar observations have been made by Fletcher in this country and by others elsewhere. The finding indicates that an unexpectedly large number of malarial infections in Malaya are, in fact, mixed, but, during the acute stage, one type or another dominates the picture and is the only one identified. The other type of parasite probably sporulates quietly in the blood stream and occurs in such small numbers that it is not evident in either thin or thick films.

Cinchona febrifuge

The chief objections to cinchona febrifuge are its varying composition and the trouble in dispensing. Solutions must be rendered more acid to ensure solution than is the case with quinine sulphate, and unless carefully filtered, are often slimy and unpleasant. Further, cinchona febrifuge contains a large proportion of amorphous cinchona alkaloids (Indian febrifuge, 45 per cent; Java febrifuge 37 per cent) and these amorphous alkaloids are relatively toxic and liable to produce vomiting, dizziness, etc. It not infrequently happens that the Tamil estate labourer refuses to swallow this preparation.

Although this is all we have abstracted, workers on any branch of malaria will find something about their special subject which is worth perusal in the report and they are accordingly referred to the original. We hesitate to use the hackneyed sentence that this report should be in the hands of all workers in malaria, because we fear it is frequently employed without much real meaning, but in the present instance it is so true that no other sentence will take its place.

In addition to the work on malaria tropical typhus occupies about twenty pages of the report, and the enteric fevers, pneumonia, diphtheria, anthrax, leprosy and tuberculosis among the diseases of major importance all receive some attention. When it is added that many bacteria have been studied, observations on vaccine lymph recorded, extract of rice polishings experimented with and a great deal of experimental work on water purification has been carried out, it will be understood that to abstract such a full report *in toto* would be quite impossible. The portion of the report devoted to routine work sheds further light on the activities of the Institute for it includes reports on bacteriology, pathology, water analysis and medico-legal work to mention only some of the subjects dealt with. It is a long time since we have had such a record of activity in our hands and the Director and his staff are to be congratulated for the amount of work they carried out in the year 1931.

ABSTRACTED FROM THE TWENTIETH ANNUAL REPORT OF THE SUPERINTENDING ENGINEER, PUBLIC HEALTH DEPARTMENT, BIHAR AND ORISSA, FOR THE YEAR ENDED 31ST MARCH, 1932

CONSIDERABLE increase in the number and size of waterworks has been made in the last ten years. In 1921-22 there were seven open municipal waterworks in the province, supplying a population of 278,570 with an average daily supply of 2,806,700 gallons. In 1931-32 there were nine open waterworks supplying a population of 477,807 with an average daily supply of 5,550,500 gallons. During the decade there has been an increase of 71.5 per cent in the population provided with a piped supply of water and of 98 per cent in the average daily supply.

Further evidence of the increase in the supply of pure water is given by a comparison of the installations in Government institutions. In 1921-22 there were four institutions with piped supplies of water with a total average daily supply of 81,800 gallons and only one of these supplies was maintained by this department. In 1931-32 there were thirteen institutions with piped supplies with an average daily supply of 519,850 gallons and six institutions with pumping plant for the disposal of sewage. Twelve out of the thirteen water supply installations and all the sewage pumping installations are in the charge of this department.

Still further evidence of progress is given by the steady improvement in the bacteriological purity of the water supplied which now, with one or two exceptions, is not inferior to the standard laid down for public supplies by the Ministry of Health in England.

In every case the improvements in the supplies as regards quantity are due to the work done by this department and in respect of purity to the joint efforts of the two Departments of Public Health and it must be remembered that the present standard will not be maintained, should there be any slackening in the continuous efforts to effect improvement.

Correspondence

ANNUAL REPORT OF THE EUROPEAN AND INDIAN MENTAL HOSPITALS, RANCHI, FOR 1931

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the May issue of the *Indian Medical Gazette* you are kind enough to ascribe the 'creed', which I have introduced into the Ranchi European Mental Hospital, as a product of my originality. I regret that I must rebut this impeachment. The idea of a 'creed' for the patients of the Ranchi European Mental Hospital came to me after reading a contribution to volume XV of *Mental Hygiene* by Dr. L. C. Marsh, assistant physician at King's Park State Hospital, Long Island, New York.

Dr. Marsh quotes the 'creed' of the King's Park State Hospital, and, after slightly altering its wording, I adopted it as a 'creed' for the Ranchi European Mental Hospital.

Yours, etc.,

OWEN BERKELEY-HILL,
LIEUTENANT-COLONEL, I.M.S.,
Medical Superintendent.

RANCHI EUROPEAN MENTAL HOSPITAL,
6th June, 1933.

SYPHILITIC IRITIS TREATED BY AN UNQUALIFIED PRACTITIONER

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—The following notes of a case may be of interest to your readers, illustrating as it does the danger of unqualified practitioners:—

B. S., a Hindu male, aged 45 years, came to me with syphilitic iritis. He could not afford a full course of treatment so consulted a *Baid* (an hereditary ophthalmic practitioner). He applied a mixture of lime, washing-soda and a *batika* of his own to the patient's forehead. In three days the forehead was deeply ulcerated and as there was no improvement in his iritis the patient returned to me for treatment, at the end of a week.

Yours, etc.,

J. R. GANGULY, M.B.

GALS,
BURDWAN DISTRICT,
25th April, 1933.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL E. H. V. HODGE is appointed as Civil Surgeon, Dacca, *vice* Lieutenant-Colonel C. R. O'Brien.

Lieutenant-Colonel B. F. Eminson, Civil Surgeon, Dharwar, to be Civil Surgeon, Hyderabad (Sind), with attached duties.

Lieutenant-Colonel M. J. Holgate, O.B.E., Civil Surgeon, Hyderabad (Sind), to be Civil Surgeon, Karachi, *vice* Lieutenant-Colonel I. D. Jones, proceeding on leave pending retirement.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's Personal Staff, with effect from the date of assumption of charge:—

To be officiating surgeon

Major W. R. Stewart, *vice* Captain (local Major) F. M. Collins granted leave ex-India.

Major J. C. Pyper, an Agency Surgeon, is posted as Residency Surgeon, Kashmir, with effect from the forenoon of the 4th May, 1933.

Major A. Y. Dabholkar, M.C., Assistant Director of Public Health, Northern Registration District, Ahmedabad, is transferred to Poona as Assistant Director of Public Health, Central Registration District, and placed in charge of the office of the Director of Public Health for the Government of Bombay, in addition to his own duties, as a temporary measure, pending further orders.

The services of Major A. C. Chatterjee are placed temporarily at the disposal of the Chief Commissioner, Delhi, for appointment as Assistant Director of Public Health, Delhi, with effect from the date on which he assumes charge of his duties.

Major C. M. Ganapathy, M.C., is appointed to officiate as Deputy Director-General, Indian Medical Service, with effect from the 19th May, 1933, *vice* Lieutenant-Colonel A. J. H. Russell, C.B.E., granted leave.

The services of Captain F. R. W. K. Allen are placed temporarily at the disposal of the Government of the Central Provinces, with effect from the date on which he assumes charge of his duties.

To be Lieutenants (on probation). 4th April, 1933

J. White, H. A. Ledger, T. F. O'Donnell, F. C. Leach, W. W. Laughland.

LEAVE

Lieutenant-Colonel A. J. H. Russell, C.B.E., Officiating Deputy Director-General, Indian Medical Service, is granted leave on average pay for 1 month and 5 days, with effect from the 12th May, 1933, combined with leave on half average pay for 2 months and 2 days.

Lieutenant-Colonel R. B. Lloyd, Imperial Serologist, is granted leave on half average pay, with effect from the 18th April, 1933, up to and including the 22nd September, 1933. He is permitted to prefix the holidays from the 13th to 17th April and to affix the recognized Pujah holidays to the leave.

Lieutenant-Colonel C. R. O'Brien, Civil Surgeon, Dacca, is allowed leave from the date of availing up to the 3rd April, 1934, namely, leave on average pay for 3 months and 4 days, and leave on half average pay for the remaining period.

Lieutenant-Colonel I. D. Jones, Civil Surgeon, Karachi, is granted leave on average pay for 1 month and 14 days followed by leave on half average pay up to 8th September, 1934, inclusive, preparatory to retirement, with effect from 31st March, 1933.

Major T. H. Thomas, Civil Surgeon, Mymensingh, is allowed leave for 6 weeks, with effect from the 16th May, 1933, or the date of availing.

PROMOTIONS

Lieutenant-Colonel to be Colonel

C. I. Brierley, C.I.E., dated the 17th February, 1933, with seniority from 28th February, 1927.

Brevet-Colonel C. A. Gill, K.H.S. Dated 28th February, 1933, with seniority 3rd June, 1922.

Captain (on prob.) W. Aitchison, M.C., to be Major (Prov.) (on prob.), 20th December, 1932.

Lieutenant to be Captain (provisional)

D. McCarthy, dated 22nd April, 1933.

RETIREMENTS

Lieutenant-Colonel R. F. Steel retires 28th April, 1933.

Lieutenant-Colonel H. P. Cook retires 28th February, 1933.

Notes.

A NEW ANTERIOR SYNECHIA KNIFE

By C. V. KRISHNASWAMI, M.R., B.S., D.O.M.S.,
F.R.C.S. (Edin.)

In cases where three-quarters or more of the pupil is incarcerated in a corneal scar and as a consequence the anterior chamber to a corresponding extent is very shallow or practically non-existent, I have experienced a great deal of difficulty in insinuating the ordinary instruments recommended for the release operation, like a Graefe's or Herbert's knife or Ziegler's knife-needle, since the sharp point either pierces the cornea or gets entangled in the iris. To obviate this difficulty I use a special knife made for me by Messrs. Down Bros., Ltd., London, the details of which are clearly shown in the illustration.

An ordinary keratome incision is made at a spot where the anterior chamber is deepest and of a size slightly larger than the width of the blade of the instrument, with the usual precautions for avoiding loss of aqueous. The instrument is then introduced through the incision until the point is well past the site of adhesion. By either depressing the handle or by a series of sawing movements the adhesion is severed. Sometimes the iris is only partly cut through, some of the fibres simply stretching before the instrument without giving way. When this occurs the instrument is partly withdrawn, pushed past the scar on the opposite side and again made to cut the iris as before. Being double-edged the instrument is used with equal facility with either hand and made to cut in either direction. The point being blunt, as are also the edges down to three millimetres from the tip, no damage to the cornea or the iris occurs.

I have operated on over fifteen cases and the instrument has served my purpose extremely well.

A HAND SLIT LAMP

By N. BISHOP HARMAN, F.R.C.S.

The value of the standard forms of slit lamps for certain ophthalmic investigations is undoubted. But the immobility of these large instruments limits their use to the consulting room and clinic.

The hand slit lamp shown has been devised with the intent of securing an instrument that could be used as readily and as easily as an electric ophthalmoscope; so that it can be carried about, and used with ease for the examination of children, and patients in bed or in their own homes. It cannot, by reason of its small size, compete with the large instruments in magnification and in resolution of fine detail. Yet it will secure a valuable view of the media of the eye as deep as the anterior part of the vitreous. The small lamp as compared with the large might be said to have

something like the relation of the two-thirds inch objective of the microscope to the one-sixth inch objective. But the small lamp gives the same effect of depth as the large lamp, so that its value for localization is certain.

In the diagram, A represents the spring and D the screw controlling the lamp centre. B indicates the position of the trunnion, C the centre contact of the lamp, and E the clamping screw. Note that in practice the filament and slit are horizontal.

The lamp is fitted to the battery handle of an electric ophthalmoscope; or a small adapter can be supplied with leads to a torch battery or other suitable source of current. At the upper end, set at right angles to the ophthalmoscope handle, is an eyepiece consisting of a triple achromatic lens giving a linear magnification of 12 X. The lens holder is so made that other powered lenses can be substituted. The case of the eyepiece is graven with a scale so that the focus of the lens, once found, can always be recovered.

Below the eyepiece, and at an angle of 45° to it, is the projection combination, forming a horizontal slit of light at a distance of one inch. It comprises a gas-filled lamp with a single strand filament, made for two cell or three cell dry batteries. The centre pole of the lamp abuts on to a spring contact, so that all lamps can be set with the filament horizontal. A powerful condensing system produces an image of the filament upon a slit fixed in the tube, so that the projection lens, an achromatic lens of some 60 dioptries, can form a clear image of this slit, free from disturbing haze or filament irregularities.

In use, the instrument must be kept steady in relation to the eye of the patient, and yet allow focusing for depth. This can be obtained by the following manoeuvre. The lamp is held by the main tube with the battery handle or adapter hanging down. There is a trigger-like spur projecting below the main tube, and this lies conveniently between the second and third fingers. The thumb rests on the top of the tube, with its end in the angle between the tube and eyepiece, the forefinger lies along the side, so that the projecting tip of the finger can rest against the patient's cheek at the lower border of the orbit. This contact gives steady support. Alternate crooking and straightening the forefinger brings the lamp nearer or further from the eye and gives focusing for depth.

Adjustments of the instrument are of the fewest, normally the eyepiece alone is likely to require setting. But the setting of the lamp bulb, in case of replacement, needs attention. The filament must be horizontal, and in the axis of the system. Whether or no this adjustment is correct, can be seen by looking at the face of the projection lens. The bright line of light should cut the lens horizontally into two equal parts. If this line is not true, the position of the filament must be altered. The lamp mount is pivoted at its front end on a horizontal axis on trunnions. At the back there are a screw and a spring on a vertical axis, the one lifting the back, the other allowing it to fall.

As the back rises, so the filament is lowered, and *vice versa*, the movement being made by releasing or screwing in the lower screw. The distance between the lamp and the condenser system can be varied by loosening the large headed screw under the lamp end of the tube, and allowing the tube to slide over the lamp stem a little. This large headed screw should be turned firmly when the adjustment has been made. Once the adjustment is obtained, it need not be altered until a new lamp is required.

It is better not to wear spectacles when using the lamp so that one's eye can be well within the shield of the ocular. It is well not to overrun the electric bulb, so when a new battery is used the switch to the rheostat should be turned on no more than two-thirds until the battery weakens.

The hand slit lamp is made by Messrs. Rayner of New Bond Street, London.

DEFORMITIES OF THE TOES

DR. STRACKER discusses the different forms of toe-deformities, their ætiology and their treatment. In cases of chronic inflammation of the joint of the great toe, the author discusses the possibility of this condition being easily mistaken for arthritis. For its treatment he recommends massage and diathermy, and internally urecidin. In acute onset, local antiphlogistic treatment with Antiphlogistine proved of great value. To lessen the pain when walking, it is recommended that two strips of wood, placed at right angles, be attached to the sole of the shoe in the area of the ball.

Priv. Doz. Oskar Stracker in the *Wiener Klinische Wochenschrift*.

AN INTRODUCTION TO X-RAY PHOTOGRAPHY

We have received from the Agfa Photo Company a very useful book entitled *An Introduction to X-Ray Photography*, by Professor John Eggert. The book deals with its subject in a general way and does not lay any undue emphasis on the products of the firm who are responsible for its publication.

The first few pages in the book are devoted to a subject of very great historical interest, namely, the reproduction of Röntgen's original paper on 'a new kind of rays', published first in 1895. There then follows a chapter on the theoretical side of the subject. This is well written and, what is more important to most readers in this country, it is well translated. The diagrams are useful and make the text easy to understand. X-ray workers will find it very helpful. The main portion of the book is devoted to the practical application of x-rays, and here technical details are described very lucidly.

We can recommend this as a very valuable and interesting publication. The Agfa Company have asked us to announce that they will be very pleased to give a free copy of the book to anyone interested in the subject who will apply to their Bombay office, Canada Building, Hornby Road.

THE MAINTENANCE OF NUTRITION

At the Thirty-sixth Annual General Meeting of Bovril, Ltd., which was held in London, on 3rd March, 1933, with the Lord Luke, K.B.E. (the Chairman), presiding, Sir James Crichton-Browne, M.D., LL.D., F.R.S., said that he did not wish to pose as monumental, but he thought he could claim to be an impressive example of what steadfast allegiance to Bovril could do, both in the maintenance of nutrition, and the prevention of obesity.

They were told by all those who ought to know that what was wanted above all things at the present moment was confidence. The Prime Minister had diagnosed the condition from which so many people were suffering as being in a state below par.

Sir James believed Bovril was well qualified to assist in correcting and alleviating that condition. Bovril braced up the nerves and imparted spirit and confidence, as was conspicuously shown in the greivous influenza epidemic through which the country had just passed. The enormous and progressive demand for Bovril during the epidemic was conclusive proof of the confidence felt in it by the people. They had proved for themselves, on the large scale, that the timely use of Bovril increased resistance to the inroads of influenza, that it afforded support during an attack, and that it was restorative in the debility—often protracted and hazardous—that followed in its train.

NEW HYPNOTIC PRODUCTS

BURROUGHS WELLCOME & Co., Snow Hill Buildings, London, E.C., have added to their list the following three hypnotic products:—'Tabloid' Phenobarbitone, gr. 1, 'Tabloid' Phenobarbitone Soluble, gr. 1, 'Tabloid' Barbitone Soluble, gr. 5. These products are issued in bottles of 25 and 100.

The two 'Tabloid' phenobarbitone products are of special value in the treatment of epilepsy and aural vertigo. They are also helpful in insomnia and nervous conditions and states of nervous excitement.

'Tabloid' Barbitone Soluble is more rapid in action than ordinary barbitone, which is one of the most effective hypnotics of the ureide series.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with re: diagnoses, etc., nor can they name practitioners by name, as any such action would constitute a breach of professional etiquette.

ATEBRIN IN THE TREATMENT OF INDIAN STRAINS OF MALARIA

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pharmacology

BIRAJ MOHAN DAS GUPTA, L.M.P.

Officiating Professor of Protozoology

and

B. SEN, B.Sc., M.B.

Research Worker, School of Tropical Medicine, Calcutta

FROM the time of the discovery of cinchona up to a few years ago, cinchona bark and the alkaloids obtained from it, particularly quinine, were the only drugs that had been used effectively in the treatment of malarial fevers. These alkaloids, although effective in many respects, are very bitter in taste, have to be given in fairly large quantities, and produce unpleasant by-effects. Besides this, although they destroy the asexual forms of different malarial parasites, they unfortunately have little effect on the sexual forms and no effect whatsoever on the gametocytes of the malignant tertian parasite. In quartan malaria their effect, even on the schizonts, is less powerful and they sometimes fail to relieve the paroxysms. Many other remedies have been introduced from time to time, but none of these have proved effective. The shortage of quinine was especially felt during the Great War and research with the object of finding a synthetic drug that could be used in its place was considerably stimulated. It was therefore a great event when, in 1926, a synthetic compound known as plasmochin (or plasmoquine) was discovered by Professor Schulemann of the Bayer-Meister Lucius research laboratories at Elberfeld. Chemically, this preparation is an amino-quinoline derivative in which a basic aliphatic radicle is united to a quinoline nucleus by a connecting link of nitrogen. This drug could be given in very small doses and has not a very bitter taste. It was at first thought to have a definite curative effect in the treatment of all forms of malaria, but later experience showed that while it was effective in curing benign tertian and quartan malaria, by itself in sub-tertian it was of no therapeutic value because it had no action on the schizonts, and some observers went so far as to say it had a provocative action. It however possessed the remarkable and unique property of destroying the crescents in the peripheral blood. In this type of malaria therefore it was still necessary to use quinine, in fact the two drugs were combined, the quinine for the schizonts and

plasmoquine for destroying the crescents, to prevent the patient from acting as a source of infection.

Although the cure of benign tertian and quartan malaria is brought about more effectively by plasmochin than by quinine, the tendency is, in order to obtain the maximum effects, to treat even these two infections with a combination of quinine and plasmochin—quino-plasmochin as it is called. With the two drugs together the relapse rate in benign tertian infections is said to be reduced from the usual 50 per cent to 3 per cent. Plasmochin is also said to have an undoubted prophylactic value whereas quinine has none. With all these qualities, however, it is very toxic and may give rise to severe toxic symptoms and for this reason it is advisable that it should be taken under medical supervision.

Schulemann and his collaborators therefore continued the work with renewed energy towards finding a more effective anti-malarial remedy, and in 1929 synthesized atebrin which originally they called 'erion'. Chemically this preparation is the di-hydrochloride of an alkylamino-alkylamino-acridine derivative. It is a yellow powder with a bitter taste, soluble to 7 per cent in water at 40°C., and like quinine it shows fluorescence under ultra-violet radiation. Since its introduction it has been extensively tried by a large number of workers in every part of the world with good results. This drug is now being largely used by medical practitioners in India, but its detailed effects on the Indian strains of malarial parasites have not been fully investigated, although Napier and Das Gupta (1932), Napier, Butcher and Das Gupta (1932) and Knowles and Das Gupta (1932) carried out detailed studies regarding its action on a small series of cases.

It has been recently shown by James (1932) and others that the action of anti-malarial drugs varies a great deal with different strains of parasites occurring in different parts of the world. James' Madagascar strain failed to react to quino-plasmochin in the same way as other strains, and there are many other examples.

In view of the fact that atebrin is beginning to be considered as effective as quinine and its use is likely to be considerably extended in this country, we took up a detailed study of the effects produced by it in a series of patients in the Carmichael Hospital for Tropical Diseases. In Bengal, malaria is endemic and in certain parts a very virulent type of malignant tertian malaria is prevalent. Our patients came from different parts of the province and probably represented many strains of parasite prevalent here. In this paper we have briefly summarized the results we have obtained by treatment of malaria with this drug. Extensive chemotherapeutic studies have also been carried out on monkey malaria, but these results will be presented in a separate paper.

The studies in connection with human malaria were mainly undertaken to determine :—

(a) The effects of the drug on the temperature and other symptoms met with in the disease.

(b) Its effects on the sexual and asexual forms of the parasites, and time taken for their disappearance from the peripheral blood.

(c) Its effect on the splenic enlargement and relapses.

(d) The effect of the drug on the pulse rate, blood pressure, respiration, and generally on the patients, and its excretion from the body.

(e) Any untoward effects produced by its administration.

The patients suffering from malaria were admitted under the senior author (R. N. C.) and a thorough physical examination was conducted immediately after admission. The peripheral blood was examined and the number of parasites, both sexual and asexual, per cubic centimetre was determined. Except in urgent cases the anti-malarial treatment was not started until the parasitic counts were fairly constant for two or three consecutive days. The pulse, blood pressure and respiration were carefully recorded. In the meantime the patients were put on a simple alkaline mixture. Daily counts of parasites in the peripheral blood during this period enabled us to watch the progress of the cases and gave us information regarding the intensity of the infection. If the parasites in the peripheral blood were scanty, these were allowed to increase till the count was fairly high, and rigors and other symptoms were produced, before the drug was administered. Atebrin was given by the mouth in tablet form, one tablet containing 0.100 gramme being given three times a day for five consecutive days. No other drug was given except a light purgative whenever necessary. No restrictions regarding diet were observed. Careful daily parasite counts were made while the drug was being administered in one series of 18 patients, but in another series of 20 cases only a rough estimation of the number of parasites in the peripheral blood was made daily.

After completion of the course the patients were carefully observed in the hospital for a fortnight, daily examinations of the blood for parasites and parasitic counts being made. If the thick and thin films were negative, in suspicious cases cultural examinations of the blood for malarial parasites were always made. In addition to the cases reported here in detail, atebrin was given to a number of out-patients and it was on these that some of the by-effects reported below were noted.

In table I the details of 18 cases are given. A study of this table will show that cases of acute infection of all three forms of malaria and some of the relapsing cases, all responded equally well to this drug. Usually the temperature begins to settle down on the second or third day of treatment and on the fourth day

there is complete disappearance of the parasites from the peripheral blood. Rigors are seldom observed after the third day of administration of atebrin. In mild cases of benign tertian infections if atebrin treatment is started on the day of the rigor, the next rigor is sometimes manifested in the form of a chilly sensation only, and in cases infected with the quartan type it does not come at all. In relapsing cases the temperature takes longer to settle down than in acute fresh infections.

A study of the table will show that the action of atebrin on the asexual forms of the parasites is gradual and not so rapid as that of quinine. It generally takes 0.6 to 0.9 gramme of the drug (*i.e.*, the administration of 3 tablets for 2 or 3 days) before the asexual forms of benign tertian disappear from the peripheral circulation. Its action on the quartan parasites is as powerful as on the benign tertian (*vide* cases 12, 13, 15 and 17). On the asexual forms of malignant tertian parasites atebrin appears to act just as readily as on the schizonts of benign tertian.

As regards the sexual forms—gametocytes—these were much more slowly acted upon than the asexual forms, the action being marked on the benign tertian and quartan gametocytes, but absent in the case of the malignant tertian gametocytes, as is the case with quinine. That the drug had no effect whatsoever on the sexual forms of malignant tertian parasites—crescents—is clearly indicated by their persistence in cases 2, 4, 9 and 10 after a full course of treatment with the drug. That the drug adversely affected the sexual forms of benign tertian and quartan parasites is obvious from a number of cases in which definite evidence of degeneration could be detected in the gametocytes.

Patient no. 8 was a young child; he vomited his first dose of atebrin, but the drug was continued and he apparently retained the later doses. The fever fell to normal after 60 hours, but subsequently rose again daily to 99° or 99.4°F.; scanty parasites also persisted.

Patient no. 9 is of special interest as he had a very high parasite count and was in danger of going on to the pernicious type. An intravenous injection of 0.1 gramme of atebrin dissolved in 1 cubic centimetre of distilled water was given at once as well as a tablet by the mouth; this was repeated on the two following days. The asexual parasites rapidly decreased in number and the temperature came down. No untoward effects were observed after intravenous administration of the drug and it would appear that the action is more rapid when given by this route.

Patient no. 10 had a mixed infection with benign tertian and malignant tertian and responded to the treatment less readily than in the case of single infections, the schizonts persisting for four days after the administration of atebrin.

Patient no. 11 was treated in the hospital for benign tertian malaria with atebrin 3 months ago, and came in with a fresh malignant tertian infection.

The observations recorded above were corroborated by results obtained in a further series of 20 cases details of which are given in table II. In this series it was not possible to enumerate the parasites daily as in the series given

in table I. The blood was carefully examined daily in every other respect, but only a rough estimate of the number of parasites in the peripheral blood was made. These cases were mostly of the acute type resembling the first series and they reacted in more or less the same way to atebirin.

Cases 3 and 9 in this series are worthy of note. Although the infections were not heavy, these patients did not react to the ordinary five days course of atebirin and very scanty malignant tertian rings could still be detected after the course. A second course of atebirin was given and with it the symptoms subsided and the parasites disappeared from the peripheral circulation. Patient no. 3 improved but left the hospital of his own accord after the second course before his blood could be finally examined. In patient no. 9, the temperature persisted after one course of treatment but subsided after the second course of two tablets twice daily for four days. In patient no. 11 benign tertian rings and trophozoites persisted after a 5-day course of atebirin. The patient was also given a second course but left the hospital before completion of the course. Such cases are difficult to explain. The possible explanation may be that in a low degree of pyrexia the parasites lodge themselves in the internal organs (only a few remaining in the peripheral blood) and are thus less readily acted upon by the drug. In cases 1, 10, 12, 13 and 15 crescents persisted after a full course of atebirin but 0.01 gramme of plasmochin twice daily for two days produced their disappearance. Patient no. 6 felt very depressed and his general condition was low after four days administration of the drug and for two days he had to be put on diffusible stimulants. A number of other patients in the two series complained of a feeling of depression and turned yellowish in colour, but this did not amount to anything serious.

In table III we have put all the chronic cases of malaria with enlargement of spleen which were treated with atebirin. In all these patients besides the usual examinations carried out in the first two series, very careful records were kept of the variations in the size of the spleen, with the treatment. Besides this the effects of the drug on the temperature have been included in the table. A study of this table will show that there was rapid reduction in the size of the spleen to practically its normal size in every case of acute infection. In long-standing cases where the spleen was hard the decrease in size was more gradual and the organ often did not come back to its normal size.

As regards the temperature, it will be seen that the chronic cases did not react so readily to atebirin treatment as the acute cases. In patient no. 3, the temperature persisted even on the 8th day and a second course of atebirin was necessary to bring it down. In patients nos. 4, 5, and 14 the temperature persisted after four days of treatment.

Relapses.—It has been urged that the most valuable property of atebirin is its power to prevent relapses and many workers have borne testimony to this effect. But in our experience quite a number of patients, at least five out of a series of 39, apparently relapsed. It must be pointed out however that, in a malaria endemic area such as this, it is very difficult to be certain whether these were fresh infections or

relapses. Two patients relapsed while they were actually under observation in the hospital after the course and parasites of the same species were found in the peripheral blood. (A number of relapses were also reported in the patients treated outside the hospital.) Even though these may not be real relapses but fresh infections, it may be noted that infection took place before the atebirin had been fully excreted from the body of the individual. Although in an endemic area like this, it is difficult to prove in the human patients that relapses actually did occur after a course of atebirin, we have ample evidence in experimental malaria in monkeys (*M. mulatta*) that the drug does not eradicate infection from the body and that relapses are common. In quite a number of these animals after a course of the drug and disappearance of symptoms and parasites from the peripheral circulation, the parasite reappeared usually within two weeks and the animal showed symptoms of the disease.

Prophylactic uses.—Atebrin is claimed to have prophylactic properties and has been used by some workers for this purpose with good results. It is said to have been continued for months without producing any untoward effects in doses of 0.1 gramme daily. It has also been combined with plasmochin for this purpose, 0.1 gramme of atebirin and plasmochin 0.001 gramme being given together daily. The prophylactic value of atebirin is still under investigation, but so far as we can see it has no more true prophylactic action than the cinchona alkaloids.

Blackwater fever.—Atebrin can be given to patients suffering from blackwater fever without ill-effects. It can also be given to patients who are sensitive to quinine and in whom administration of quinine produces hæmoglobinuria.

Pulse rate, blood pressure, respiration, etc.—In a series of nine patients the effects of atebirin on the blood pressure, pulse rate and respiration were recorded. Careful records of these were obtained for a few days preceding the administration of the drug and these were compared with those obtained both when the patients were actually taking atebirin and a few days after the cessation of the drug. So far as possible the readings were taken under exactly the same conditions and at a particular time of the day with due regard to food, posture, temperature, etc.

So far as the blood pressure (systolic and diastolic) is concerned there was a slight lowering varying from 5 to 12 millimetres of mercury in some patients. In others there was no change whatsoever. The pulse rate and respiration also showed no appreciable changes when the patients were under the effect of the drug. From these results one is justified in concluding that atebirin has little, if any, depressing effect on the cardio-vascular system.

in the majority of the patients. We have given the drug to patients suffering from endocarditis and myocarditis without ill-effects.

Excretion.—In a series of patients we worked out the excretion of the drug. The drug is mostly excreted by the kidney and its presence can be roughly detected in the urine by production of the characteristic yellow colour on addition of an acid. The test suggested by the makers is to extract the alkalinized urine with ether, and dissolve the residue resulting from the evaporation of ether extract in strong sulphuric acid, when a yellow colour appears. This latter test is more accurate, and we actually used a modification of it. The urine was first treated with lead acetate to remove all other matter and the lead was removed from the filtrate by the addition of ammonium sulphate. The filtrate was then extracted with ether and tested with acid in the ordinary way. The drug appears in the urine on the second day after administration and can be detected up to 15 or 20 days or even longer. The excretion is not regular and may stop for a day or two and then reappear. Our observations on Indian patients confirm the view that there is some tendency towards cumulation of the drug in the body. Atebrin undoubtedly persists in the body for a much longer period than quinine or plasmochin. If excretion is hindered there is a tendency for the appearance of the dye in the skin which assumes a yellowish tinge.

Untoward and toxic effects.—Atebrin unlike plasmochin is not a very toxic drug. Double the usual dose of 0.3 gramme per day (i.e., 0.6 gramme in 24 hours) can be tolerated, but larger doses may produce gastro-intestinal irritation. In spite of the tendency referred to above of cumulation of the drug in the system we gave two 5-day courses of the drug with a few days interval between without producing any toxic effects, and with therapeutic benefit. Some patients complained of slight pain or a sensation of uneasiness in the epigastric region soon after taking the drug. This generally started on the second or third day and persisted as long as the drug was being administered. The pain was never so severe as that produced by plasmochin. In none of our series did we get the severe abdominal pains described by Green (1932). A number of our patients complained of headache and loss of appetite while the drug was being given, but this also passed off when atebrin was stopped. In some patients a profound feeling of general depression started on the third day of treatment and persisted for several days after the drug was stopped. The patient felt as if he had 'no life in him' and had no desire to make physical exertion and wished to remain lying down. In some of the patients diarrhoea was produced on the second and third days of treatment and persisted while the drug was being given. The diarrhoea was of a mild type and no particular treatment was necessary. It stopped with the cessation of the

drug. In a few patients, especially those who were obese, palpitation occurred which was quite distressing but stopped when the drug was discontinued and in one patient cardiazol had to be administered. In one case mental disturbances were reported to have occurred.

A yellow staining of the skin and conjunctiva occurred in several of our patients, but the coloration as a rule was very slight and in none of the patients did it amount to a jaundice-like appearance.

Summary and conclusions

From a study of this series of patients one can draw the following conclusions:—

(1) Atebrin is an effective drug in the treatment of Indian strains of malaria. Its destructive action on the asexual forms of benign tertian, malignant tertian, and quartan types of malaria is about equal, the schizonts disappearing from the peripheral circulation after 0.6 to 0.9 gramme of the drug, i.e., the administration of 3 tablets of 0.1 gramme for 2 or 3 days.

(2) The sexual forms or gametocytes are more slowly acted upon than the asexual forms. The gametocytes of the benign tertian and quartan types are readily destroyed and degenerative changes can be observed in them shortly after the administration of the drug is started. The gametocytes of the malignant tertian type—i.e., crescents—are not touched at all.

(3) The drug is effective in doses of 0.1 gramme three times a day, the course lasting for five days, making a total of 1.5 gramme of the drug for the cure. In the majority of patients such a course is effective, but in a few of the persistent ones it may have to be repeated after a few days interval. The drug can also be effectively given intravenously in doses of 0.1 gramme dissolved in 1 to 2 cubic centimetres of distilled water when the number of parasites in the peripheral blood is large.

(4) In chronic types of malaria the drug is effective and produces a rapid reduction in the size of the spleen.

(5) Atebrin is reported to prevent relapses, but the evidence at our disposal shows that this is not the case with Indian strains of malaria. Its prophylactic value is very similar to that of the cinchona alkaloids.

(6) In blackwater fever and in patients in whom administration of quinine produces hæmoglobinuria atebrin can be safely given.

(7) The blood pressure is lowered in some patients during the administration of the drug, but in the majority there is no effect. The pulse rate and respiration are not markedly affected. It has been used in patients suffering from endocarditis and myocarditis without ill-effects.

(8) The drug is largely excreted in the urine and can be readily detected in it. The excretion is not regular, occurs in fits and starts, and goes on for three weeks or longer. There

A CASE OF TROPICAL TYPHUS SEROLOGICALLY RELATED TO 'SCRUB TYPHUS' OF THE FEDERATED MALAY STATES

By C. DE C. MARTIN, M.B., Ch.B., D.T.M. & H.

MAJOR, I.M.S.

Civil Surgeon, Rangoon (East)

and

L. A. P. ANDERSON, M.A., M.D., D.P.H., D.T.M. & H.

LIEUTENANT-COLONEL, I.M.S.

Director, Pasteur Institute, Rangoon

IN a recent publication, Kundu (1932) described a case of typhus fever contracted in Burma, the clinical diagnosis being confirmed by a strongly positive Weil-Felix reaction with proteus X19. In the conclusions to his paper Kundu refers to the possibility of the tropical

(Continued from previous page)

is a distinct tendency towards cumulative action of the drug in the body.

(9) Atebrin produces certain untoward effects which are not however serious. A profound feeling of general depression occurs in some patients. A slight yellow tinge of the skin and conjunctiva was observed particularly in those patients in whom excretion from the kidney is hindered for some reason. Slight epigastric pain, a feeling of uneasiness in the stomach, headache and loss of appetite and diarrhoea sometimes occur when the drug is being administered. These as a rule stop when the drug is stopped.

(10) The action of atebrin closely resembles that of the cinchona alkaloids and the introduction of this drug is a distinct advance in the treatment of malarial fevers in India. The price at present is too high for its use by the people in general.*

(*The present price of atebrin is Rs. 49-8 for 300 tablets, that is Rs. 2-8 for one 'treatment' of 15 tablets; of this sum 23 per cent, or 9 annas, is duty. It is hoped that the government will shortly see their way to allow this useful drug to be brought free of duty into India, as at present it is into Ceylon.

A single 'treatment' can be purchased, but the price is a few annas more per 'treatment'. On the other hand the makers are prepared to quote a considerably lower rate for quantities of 5,000 tablets or more.—EDITOR, I. M. G.)

typhus which occurs in Malaya overlapping into Burma, and suggested that further investigation in the future would probably reveal the presence in this country of more cases of fever of this type.

Experience in Malaya has shown (Fletcher, 1930) that in that country 'tropical typhus' of two distinct serological varieties is met with. The first of these occurs among the urban population and is designated the 'W' group or 'shop typhus'. The serum of patients suffering from this type of the disease gives a positive agglutination reaction with the ordinary X19 strain of proteus. The other variety, occurring among the rural population, is called the 'K' group or 'scrub typhus' and differs, *inter alia*, from the urban variety in that the serum of the patients does not agglutinate proteus X19 but gives a positive Weil-Felix test with the 'Kingsbury' strain of proteus, proteus XK. To this latter group of typhus-like fevers, according to Fletcher, belongs also tick typhus of India.

Apparently the case described by Kundu corresponds to the 'shop typhus' met with in Malaya.

Cases of 'tick typhus', i.e., typhus-like fevers apparently conveyed by the bite of ticks and probably also of mites, have been reported relatively frequently from India (Megaw and Rao, 1928; Christian, 1932). In such cases the Weil-Felix reaction has been found extremely variable, the majority being negative when proteus X19 is used. The 'Kingsbury' strain, proteus XK, does not appear to have been actually employed in the diagnosis of such cases in India, except in the one case reported by Christian (1932), where the serum of the patient, which gave a negative result in a dilution of 1/25 with the non-motile 'O' variant of proteus X19, weakly agglutinated—perhaps in hardly significant titre—the 'O' variant of proteus XK. It is therefore not certain to what extent, if any, the typhus-like fevers of India fall into two serological groups corresponding to the 'W' and 'K' groups of similar fevers occurring in Malaya.

So far as we are aware, no cases of tick typhus nor cases of typhus-like fevers corresponding to the 'K' group, or 'scrub typhus', of the Federated Malay States, have hitherto been reported from Burma. The following case, which clinically resembled the one and which laboratory investigation showed to be related to the other, may therefore be of interest, not only as showing that such cases may be met with in Burma but as lending support to Kundu's suggestion regarding the possible identity of these fevers here and in Malaya:

HISTORY AND CLINICAL FEATURES OF THE ILLNESS

Mr. G. F. B., an European, aged 40 years, was admitted under the care of one of us (C. de C. M.) in the Rangoon General Hospital on 27th December, 1932. The previous history was that he was touring in the forests of the Thayetmyo district of Upper Burma

when on 18th December he felt feverish and developed severe pains in all his joints accompanied by a severe frontal headache. He had suffered from dengue fever on previous occasions and thought that this was a similar attack.

On 22nd December he returned to headquarters and reported to the civil surgeon, Thayetmyo. His temperature rose gradually to 102°F., while the pulse rate remained round about 70.

On the day after his return to Thayetmyo, a profuse rash appeared all over his body and his general condition became worse, so he was transferred to Rangoon and was admitted to the Rangoon General Hospital on 27th December, 1932, the ninth day of the illness.

On admission he stated that he had had T.A.B. inoculation in November 1931, had last suffered from dengue in July 1932, and had severe attacks of malaria in 1922 and 1923.

By the 2nd January, the spleen had further enlarged and appeared to be very tender, and the liver could now be felt two fingers' breadth below the costal margin. The left heart was enlarged, and the action so bad that strophanthin, gr. 1/200, was given intravenously with benefit. The rash at this time—about the 15th day of the illness—began to fade and was replaced later by a general hyperæmic condition of the skin, which showed definite staining.

From the 4th January (17th day of the disease) the temperature began to fall by lysis, reaching the normal line on the 7th January. With the defervescence the general condition improved. Consciousness returned and the pulse became more regular.

By the 16th January the liver had become normal, the spleen only just palpable, and the last signs of the staining of the skin had disappeared.

Patient G. F. B. Typhus Fever

No history giving any clue to the possible source of infection in his present illness was obtained from the patient himself, but his wife stated that the day he returned from the jungles, he complained of a painful insect bite on the forearm. He did not know what the biting insect was, nor did he know when he had been bitten.

On examination, his temperature was 102°F., pulse 108 and respirations 24. The whole trunk and limbs were covered with a large and profuse, deeply-pigmented, maculo-squamous rash. There was no rash on the face nor on the palms and soles. The face was flushed, conjunctivæ injected, tongue coated, spleen enlarged four fingers' breadth below the costal margin, liver not palpable. The heart was irregular and showed extra-systoles.

The blood was repeatedly negative for malaria parasites.

From the day of admission until the 3rd January, the temperature ranged between 101°F. and 103°F., the four-hourly chart showing a maximum rise on one occasion to 104.2°F. The pulse throughout seldom rose above 108 and was more often between 80 and 90.

The patient appeared to be acutely ill throughout and soon fell into a low muttering delirium which on occasions became wild and could only be controlled by morphia.

The heart was slow, feeble, and markedly irregular, with dropped beats, and the pulse of low tension.

From now on he made a rapid and uninterrupted convalescence and was discharged from hospital on 25th January, 1933.

The clinical features of the illness, together with the history of an insect bite and the negative character of the serological findings during the patient's stay in hospital, appeared to justify a tentative diagnosis of tick typhus.

Serological investigations

In attempting to arrive at a diagnosis in G. F. B.'s case, which clinically appeared to rest between enteric group infection or some form of typhus fever, the latter being more probable, the patient's serum was examined at intervals during the course of the illness, on three occasions by the Widal test for evidence of enteric fever, and on two occasions by the Weil-Felix test for evidence of typhus fever.

For the Widal tests both Felix's 'qualitative receptor analysis' method (Felix, 1930) and Dreyer's method were used. The Widal tests were complicated by the fact that the patient had received T. A. B. inoculation about a year previously. The results of all the tests are given in tabular form below:

Widal tests for enteric group infection

Specimen taken on	Day of disease	Method used	RESULTS				
			Serum dilution	T 'H' 901	T 'O' 901	Para A 'H' A6	Para B 'H' B2
24-12-32	6th	Felix's	1-25	++H0	++0	±0	+0
			1-50	++H0	+0	—	±0
			1-100	+H	—	—	—
			1-200	±H	—	—	—
			Control	—	—	—	—
30-12-32	12th	Felix's	1-25	++H	++0	++H	+H
			1-50	++H	+0	++H	+H
			1-100	+±H	—	+H	+H
			1-200	+H	—	+H	—
			Control	—	—	—	—
5-1-33	18th	Felix's	1-25	+++H	++0	++H	+++H
			1-50	++H	++0	++H	+++H
			1-100	+H	++0	+H	+++H
			1-200	±H	±0	—	+++H
			Control	—	—	—	—
			Standardized suspension	Dilution giving standard agglutination		Reduced titre 'R. T.'	
30-12-32	12th	Dreyer's	<i>B. typhosus</i> 'H' ..	1-170		21	
			<i>B. para A</i> 'H' ..	1-680		170	
			<i>B. para B</i> 'H' ..	1-50		10	
			<i>B. typhosus</i> 'O' ..	1-15		0.9	
			<i>Bact. artrycke</i> 'O' for Para B 'O'.	Negative		0	
5-1-33	18th	Dreyer's	<i>B. typhosus</i> 'H' ..	1-250		31	
			<i>B. para A</i> 'H' ..	1-500		125	
			<i>B. para B</i> 'H' ..	1-75		16	
			<i>B. typhosus</i> 'O' ..	1-17		1	
			<i>Bact. artrycke</i> 'O' for Para B 'O'.	Negative		0	

Note.—+++ denotes complete agglutination; ++ strong, almost complete; + partial, visible with the naked eye; ± trace of agglutination, visible with lens; — no agglutination. H=floccular agglutination; 0=granular, small-flaking, agglutination.
For interpretation of Dreyer's test see Gardner (1931).

The Weil-Felix tests were carried out with the same technique as that used for Felix's method in the Widal tests, on the 12th and on the 18th day of the disease. Living cultures of proteus OX19, which gives only small-flaking agglutination, were used. The results were entirely negative in dilutions from 1 in 25 to 1 in 200.

Comments.—In assessing the diagnostic value of the Widal tests, the 'H' agglutination given by the patient's serum must be discounted, in view of the comparatively recent inoculation with T. A. B. vaccine. The lack of significance of this agglutination is further supported by the fact that repeated tests showed no marked increase in the titre in respect of any one member of the enteric group.

The only finding which was at all suggestive of enteric infection in these tests was the definite rise in the titre of *B. typhosus* 'O' agglutination, which showed strong positive in 1—100 by Felix's method at the third test with the 18th day specimen. According to Felix (1930) such a reaction is at least highly suggestive of enteric group infection even in an inoculated patient. One of us (L. A. P. A.) has, however, observed titres of this magnitude not uncommonly in the sera of healthy inoculated persons in this country, indeed also occasionally in healthy uninoculated persons, when using the highly sensitive culture T 'O' 901 with Felix's technique. Moreover, the results obtained by Dreyer's technique, using the highly agglutinable Oxford standard suspension of *B. typhosus*

'0', entirely negatived the presence of '0' agglutinins in any significant quantity in the patient's serum.

From these tests, therefore, a negative report was given as regards enteric group infection.

The Weil-Felix test, using proteus OX19, was completely negative; consequently no diagnosis of the case by serological methods could be made at this time with the materials at our disposal.

Some time after the patient had completely recovered and had left the hospital, the Pasteur Institute, Rangoon, received, through the kindness of Dr. P. H. Martin of the Institute for Medical Research, Kuala Lumpur, cultures of the 'Kingsbury' strain of proteus, proteus OXK.

This strain, the history of which is given by Felix and Rhodes (1931), reacts specifically with the serum of patients suffering from that group of 'tropical typhus' which has been referred to above as occurring among the rural population of the Federated Malay States and which is designated group K (= rural group), or more recently 'scrub typhus' (Fletcher, 1930); the serum of patients suffering from this variety of typhus fever invariably fails to react with the usual X19 strain.

Some of the serum of patient G. F. B., drawn on the 18th day of the disease, was still available, having been kept in the refrigerator since its receipt in the Institute. After the proteus OXK cultures received from Kuala Lumpur had been found to conform to the necessary biochemical and serological tests, the serum of the patient was put up against this strain.

The test was carried out by Dreyer's method using living saline suspensions, with 18-24 hours incubation in the water-bath at 37°C. The result was as follows:—

Dilutions of serum	Degree of agglutination with strain OXK	Type of agglutination
1-25	Total	'0'
1-50	Total	'0'
1-125	Total	'0'
1-250	Total	'0'
1-500	Total	'0'
1-1,000	Total minus	'0'
1-2,500	Standard minus	'0'
1-5,000	Negative	..
Control	Negative	..

A further test on the same day, using proteus OX19, was again completely negative in all dilutions from 1-25 upwards.

Comments.—The serum, which repeatedly failed entirely to agglutinate proteus OX19, gave partial agglutination, easily visible with the naked eye, in a dilution of 1-2,500 when tested with the 'Kingsbury' strain, proteus OXK. This titre is comparable to those observed in cases of 'scrub typhus' occurring in

Malay. There appears to be little doubt that this case was, in fact, 'tropical typhus' and belongs to the same group of this disease as the 'scrub typhus' of Malaya.

Summary and conclusions

1. A case of continued fever contracted in Burma and exhibiting symptoms and signs suggestive of 'tropical typhus' is described.

2. Repeated Widal tests carried out at intervals during the course of the illness gave no evidence of enteric group infection, while the Weil-Felix test, using proteus OX19, was persistently negative.

3. The serum of the patient, taken on the 18th day of the illness, strongly agglutinated the 'Kingsbury' strain of proteus, OXK, a strain of proteus which reacts specifically with the serum of cases of 'scrub typhus' occurring in Malaya.

4. It is considered, therefore, that this case was one of tropical typhus belonging to the same serological variety of the typhus-like fevers as the 'K' group, or 'scrub typhus', of the Federated Malay States.

5. The clinical features of the case, with a history of a painful insect bite, and the later serological findings, strongly suggest that we are dealing here with a variety of tick typhus, forming another of the rural group of typhus-like fevers, a group which includes tick typhus of India on the one hand, and scrub typhus of Malaya on the other.

6. So far as we are aware, this is the first occasion on which this variety of tropical typhus has been reported in Burma and demonstrated serologically. We suggest that the introduction and use of the 'Kingsbury' strain of proteus, in addition to proteus X19 for the serological diagnosis of typhus-like fevers in this country, will probably show that, here, as in Malaya, there exist two groups of these fevers, one of which has hitherto remained undiagnosed by laboratory methods.

HISTORICAL

Sputum.—Eosinophiles were first noted in the sputum of asthmatics in 1889 by Von Muller and by Gollasch. In 1892 Aranson and Phillip found that 66 per cent of the cells in the sputum of a patient with asthma were eosinophiles. Weiss (1891), Lewy (1900), Heineke and Deutschmann (1906), and Von Strumpell (1908) found eosinophiles in the sputum in cases other than asthma and considered that the presence of eosinophiles in sputum was not specific for asthma.

Blood.—Fink (1890), Neusser (1892), Mandybur (1892), and Von Noorden (1892) found that at the time of the attacks there was usually an increase in the number of eosinophiles in the blood. Von Noorden reports a case with 33 per cent of eosinophiles during an attack and 5 per cent during a free interval. Gabritschesky (1893) found a well-marked eosinophilia in three cases. Zappert (1893) and Wolff (1900) each reported the finding of about 10 per cent of eosinophiles in the blood of asthmatics during intervals of freedom from attacks. Billings (1897) had a case with 54 per cent of eosinophiles. Herrick (1911) reported a case with a total leucocyte count of 57,000 of which 77 per cent were eosinophiles. Staubli (1911) considered that eosinophilia was a constant sign of asthma.

Variability of the sign.—It will be seen that presence of eosinophiles in the sputum and the blood of asthmatics has long been known. The marked variability of this sign in different cases and at different intervals in the same case requires a passing reference before the causation of eosinophilia and its diagnostic value is discussed. Von Noorden (1892) reports a case with 33 per cent eosinophiles during an attack and only 5 per cent during a free interval. On the other hand Heineke and Deutschmann (1906) observed during an asthmatic attack a decrease in blood eosinophilia from 2.1 to 0.4 per cent. Bray (1931) records a case in which there was an eosinophile count of 18 per cent of a total leucocyte count of 11,600 in the free interval dropping to an entire absence of eosinophiles in a count of 23,700 leucocytes during the attack. Gillespie (1930) found that during the attack the eosinophilia percentage in a majority of cases fell to nearly half of that during the free intervals. Rackemann (1918)

in a clinical study of 150 cases of asthma stated that the percentage of eosinophilic leucocytes in the blood did not vary during and between the attacks, and that increased blood eosinophilia was not a constant sign of asthma. Huber and Koessler (1922) stated that 25 to 30 per cent of all cases of asthma were bacterial in origin and that blood eosinophilia in this group of cases varied exceedingly sometimes being very marked, sometimes slight, and sometimes even completely absent. Brown (1927) stated that eosinophilia in bronchial asthma was by no means a constant finding. Sputum eosinophilia is subject to the same variations. Knott (1930) found that out of 132 cases the sputum was eosinophilic in 85 cases. In our series of 150 cases only 36 had eosinophiles in the sputum.

THE CAUSATION OF EOSINOPHILIA

I. The earliest theory about the causation of eosinophilia is that of Neusser who in 1892 stated that eosinophilia was produced in response to the increased activity of glands supplied by the sympathetic nervous system. His views have never been confirmed. Eppinger, Falta, and their co-workers (1907) on the other hand saw in eosinophilia a symptom of increased vagus tone. This view has some adherents. Hajos and Enyedy (1925) in a study of 30 cases of asthma concluded that eosinophilia was an early indicator of vagus irritability.

Bezançon and Bernard (1930) suggest that eosinophilia may be evidence of the vagotonic state. McDowall (1930) suggests that eosinophilia in cases of asthma may be due to increased secretion of insulin brought about by increased vagus tone. He argues his point on the following lines: (i) that both McLeod and Clark have shown that stimulation of the vagus causes a fall of blood-sugar level, presumably by causing the pancreas to secrete insulin; (ii) that Cameron has shown that asthmatics commonly have a low blood-sugar level; and (iii) that Lawrence has shown that in diabetes the administration of insulin causes eosinophilia.

II. The causation of eosinophilia in asthma has been looked upon from an entirely different point of view since this disease has been associated with the phenomenon of anaphylaxis. In 1905 Stehastnyi showed that blood and serum injections into animals were often followed by a considerable increase in the number of eosinophiles in the blood. In 1910 Moschowitz noted the association of eosinophilia with anaphylaxis. He took the position that anaphylactic disease was invariably associated with eosinophilia, that asthma was also associated with eosinophilia, therefore asthma was the result of anaphylaxis. The true connection between eosinophilia and the anaphylactic process was first clearly recognized by Schlecht in 1910. He observed marked increase in the number of eosinophiles after serum injection and he

ascribed this phenomenon to the introduction of the foreign protein. In 1912 Schlecht and Schwenker found that eosinophilia developed regularly on re-injection of egg albumin, serum albumin or globulin into animals which had been sensitized by a previous injection of a minute dose of the same substance. They discovered also the eosinophilic infiltration of the bronchi in the lungs of anaphylactic guinea-pigs. Since then the consensus of opinion has been in favour of considering eosinophilia as a manifestation of a condition of allergy that has been shown to exist in asthma, hay fever, urticaria, etc. Hiss in 1914 considered that the eosinophile diathesis was the basis of the allergic condition.

On the basis of Schlecht and Schwenker's work eosinophilia was considered as a protective reaction of the organism against certain definite decomposition products of protein origin. In this connection the views of Berger, Alexander, and Meulengracht and Holm require attention. Berger (1916) noted that when a protein which an infant had never previously ingested, was introduced into that infant's diet there was usually an increase in the percentage of eosinophiles in the general circulation. Alexander (1928) has suggested that protein-like substances are broken down through the action of eosinophiles. Meulengracht and Holm (1930) have shown that ingestion of raw liver constantly induces an eosinophilia in individuals suffering from certain diseases, but liver or liver-extract does not do so. Huber and Koessler (1922) are in complete agreement with Schlecht and Schwenker and believe that most clinical eosinophilias have to be considered as the reaction of a person in the state of allergy. In asthma they believe that 'it is evidence of (a) the allergic type of asthma due to sensitization with proteins of antigenic character, or (b) of an intoxication with higher peptones. If constantly absent it forms, together with other clinical symptoms, strong evidence that asthma is due to intoxication with lower peptones or with the amines, or that the bronchospasm is produced by extraneous factors, pressure on the vagus by tumours or aneurism'.

Zambusch (1927) suggested that eosinophilia in allergic conditions was due to defective splenic function, normal action of the spleen being to 'hem in' the eosinophile cells.

III. Coates and Ersner (1930) consider the eosinophilia a factor in all inflammations irritative rather than infective in character and it is a constant component when the tissues are oedematous. Bezançon and Bernard (1930) in their review of the French literature on the subject considered that the eosinophile is a connective tissue cell and is associated with the repair that takes place at the site of injury. Local eosinophilia first occurs at the site of reaction and increase in the eosinophiles of the blood takes place secondarily.

Having considered the different views about eosinophilia we now proceed to give our views on the subject. We will begin by taking into consideration the responses in the blood to the injections of various foreign substances. The antigens injected into the body consist of two classes, (i) those of plant origin and (ii) those of animal origin. The plant proteins injected into the body are generally dead bacilli and tissues react against them by local capillary dilatation followed by migration of the polymorphonuclear leucocytes. The dead bacilli are taken up by these neutrophils and destroyed, and at the same time substances are produced which lyse and break up the dead bacteria into soluble non-toxic bodies. Following the injections of dead bacilli the animal shows a temporary increase in the number of polymorphonuclear cells in the blood, at the same time various immune substances, agglutinins, lysins, and bactericidal substances can be demonstrated. We can therefore inject plant proteins into an animal body and get a series of responses called immunity. On the other hand when we inject foreign animal proteins into an animal the response is differently expressed depending on whether the substance injected is a mass, like cells, or in a soluble state. When particles like cells are injected there is a local response containing many eosinophile cells and the foreign cells themselves are broken up and destroyed. In time there is a general increase in the eosinophiles of the blood and lytic substances are found, such as haemolysins. When soluble particles or particles in the colloidal state are injected the eosinophiles increase in the blood and various substances such as precipitins form to deal with the foreign protein. When large doses are injected such as antidi-phtheritic serum, an increase in the eosinophiles is observed followed by toxic phenomena which are known as serum sickness.

Hitherto we have been dealing with large particles or particles in the colloidal state, we can now consider the injection of crystalloidal substances derived from these plant and animal proteins. The best known examples are histamine and tyramine which are obtained from the amino-acids of plants and animals. The injection of both these substances causes a temporary increase in the eosinophiles of the blood, while on the other hand pilocarpine which is a plant alkaloid also gives rise to an eosinophile response. Most of the plant alkaloids, such as morphine, quinine, and strychnine, do not cause an increase in the percentage of eosinophiles in the blood. We therefore see that eosinophilia is a response to the injection of foreign animal protein as well as of certain amines which can be derived from the amino-acids of plants or animals. On the other hand increase in polymorphonuclear cells is a response of the body to deal with particles of plant proteins. Most of the plant alkaloids do not cause a response of either type of cell.

The next point to be considered is the difference in the reactivity of different individuals. To illustrate this point we may here quote a small series of experiments (table I). Repeated injections of peptone, aolan, and egg albumin were given to six patients, two getting peptone injections, two aolan, and the remaining two egg albumin. On comparing the blood counts in case 1 with 2, case 3 with 4, and case 5 with 6 it will be evident how different individuals react differently to the same substance. In case 1 peptone injections did not cause any appreciable rise in the eosinophile count, while the same substance gave rise to a marked eosinophilia in case 2. The same thing can be seen in cases of egg albumin and aolan.

the attacks subsided. Signy and Bray (Bray, 1931) in 100 cases of children found the eosinophile percentage varying from 4 to 7, the highest being 23.

Spangler (1925) considers the eosinophilic index an important guide in determining the degree of hypersensitivity of a patient, but Baagoe (1928) finds that there may be a marked sudden rise in the eosinophilic counts of asthmatics without any associated symptoms and on the other hand that repeated severe paroxysms may occur in other patients with little or no rise in eosinophilia. Van Leeuwen and Van Nickrek (1928), after a study of 203 patients, also discredit the value of eosinophilia as an index of the severity of the condition and the

TABLE I

Experiment number	Substance injected	Blood count before injection	BLOOD COUNT AFTER			
			first injection	second injection	third injection	fourth injection
1	Peptone	Total leucocytes 10,000	10,200	12,000	9,000	..
		Total eosinophiles 1,000	918	2,400	1,260	..
2	Peptone	Total leucocytes 26,000	26,000	15,000	15,000	..
		Total eosinophiles 0	2,080	7,000	5,000	..
3	Aolan	Total leucocytes 12,000	7,000	10,000	10,000	7,000
		Total eosinophiles 600	600	800	2,000	1,000
4	Aolan	Total leucocytes 20,000	18,000	20,000	12,000	28,000
		Total eosinophiles 2,000	1,800	2,000	6,000	14,000
5	Egg albumin ..	Total leucocytes 12,000	14,000	15,000	11,000	..
		Total eosinophiles 800	1,000	2,000	1,100	..
6	Egg albumin ..	Total leucocytes 15,000	20,000	25,000	25,000	..
		Total eosinophiles 600	2,000	12,500	16,000	..

The value of the eosinophile count.—Cooke (1921) reports eosinophiles in excess of 4 per cent in 63 per cent of a series of 90 carefully-studied cases. According to him blood eosinophilia is therefore suggestive evidence of bronchial asthma, but its absence does not preclude such a diagnosis. Spangler (1925) considers that increased eosinophilia in bronchial asthma points to the presence of an allergic factor in the disease. Brown (1927) in 193 cases of asthma found the average eosinophile count, both in sensitive and non-sensitive cases, to be 7 per cent—this is higher than the average obtained in cases suffering from hay fever (6 per cent), colds (3 per cent), eczema (5 per cent), and urticaria (4 per cent). Rackemann and Colmes (1929) found more than 4 per cent of eosinophiles in the blood of practically all of 150 patients with asthma. Baagoe (1928) in the study of eosinophiles of normal children found that the percentage varies from 0 to 12 with an average of 3 per cent and slowly falls as the child gets older. In asthmatic children an increase occurred in the eosinophiles after

progress of the patient. Brown (1927) found that some definitely sensitive patients had no eosinophilia either during or between attacks, whilst some of the highest percentages were in non-sensitive or bacterial cases. He concludes that sex, age, and sensitivity play no part in determining the degree of eosinophilia. In our series of cases also some of the highest eosinophile counts were encountered in the bacterial cases.

So that it will be seen that there is a good deal of confusion regarding the value of this sign in asthma. We will now proceed to discuss this point.

The material we studied consisted of 150 individuals who were suffering from typical spasmodic asthma. Many of our patients had also various infections common in the tropics, which made the problem still more difficult as the leucocyte count varied from 5,000 to 37,000 per cubic millimetre. Under such conditions it was obviously impossible to use percentages; these would be meaningless unless one did the total count as well. This has been done

throughout and the eosinophiles given as a number per cubic millimetre and not as a percentage. At the same time it is necessary to define what we mean by a normal count and to give the limits of leucopenia and leucocytosis. In Bengal there are two common diseases that produce leucopenia, namely kala-azar and chronic malaria with splenomegaly. Leucopenia is marked in kala-azar, we have therefore chosen this disease to establish what we mean by leucopenia. Table II shows the counts of 101 individuals who were suffering from kala-azar in which parasites were found either by spleen puncture or blood culture. Many of these cases were also suffering from hookworm infection.

and were admitted into the Medical College Hospital. These cases were either of primary pneumonia or of pneumonia secondary to debilitating diseases like malaria, kala-azar, and hookworm. The leucocyte count varies from 5,000 per cubic millimetre to 50,000. Taking 8,000 leucocytes as the lowest normal count there were 11 cases that showed leucopenia, the majority of these must have been secondary to diseases like kala-azar. The next point to decide was, what should be the upper limit of a normal count, because it is well known that these cells vary in number according to the meals taken during the day and to other causes. We have selected 12,000 as the upper limit of a normal count. In these cases there were 72

Out of 101 cases only 8 cases show an eosinophilia of over 5 per cent.

We are indebted to Dr. L. E. Napier and the late Dr. J. B. McVail for the use of their research material to compile this table. You will see that the lowest count is 1,500 leucocytes per cubic centimetre and the highest count was 7,500. Taking a 5 per cent basis of the eosinophile count which is shown by the 'step line' it will be seen that in only 8 cases was there over 5 per cent of eosinophilia, in spite of the fact that the majority of these patients had hookworm infection as well. McVail (1922) pointed out that in hookworm infections, if leucopenia is present, the eosinophiles are of little practical use in the diagnosis of this helminthic infection. We may therefore put a limit of leucopenia to a count below 8,000 leucocytes per cubic millimetre.

We will now consider what we will take as the upper limit of a normal count, for this purpose we have chosen pneumonia as a disease illustrating the phenomenon of leucocytosis. Table III shows the leucocyte count of 123 individuals who were suffering from pneumonia

individuals who showed a leucocytosis varying from 13,000 to 50,000 per cubic millimetre. In this series there were only 18 individuals who showed an eosinophilia above 5 per cent. The step line shows the number of eosinophiles per cubic millimetre of blood that constitutes the 5 per cent limit. We will therefore establish as a normal count the variations between 8,000 and 12,000 leucocytes per cubic millimetre, considering any number below that as a leucopenia and above it as a leucocytosis. With leucopenia the number of eosinophiles per cubic millimetre is not a reliable indication of hookworm infection.

We will now study the effect of helminthic infections on the number of eosinophiles per cubic millimetre of blood. Table IV consists of 100 individuals who were suffering from hookworm infection; eggs were found in the stools.

We are indebted to Dr. P. A. Maplestone for supplying us the data for our tables. We will see that for these individuals the count varies

from 3,000 to 17,000 leucocytes per cubic millimetre and that in this series 72 out of 100 showed an eosinophile increase above 5 per cent. Of the remaining 28 individuals who did not show this increase in eosinophiles, 18 showed a leucopenia; this evidence of depression of the bone-marrow function accounts for the reduction in the eosinophile count.

The high blood eosinophilia in cases of filariasis with microfilaria present in the blood contrasts markedly with the absence of this sign in cases with no microfilaria in the blood. Dr. Sundar Rao has kindly supplied us with the total and differential leucocyte counts of 200 cases of filariasis. Amongst the cases with microfilaria present in the blood 62 out of 100 show an eosinophile count over 5 per cent, while only 20 out of 100 cases with no microfilaria show this increase. (The tables showing these counts will be found on page 308 in the June number of the *Gazette*.)

organism produce histamine when cultivated in broth. The local production of the histamine in the bronchi would act directly on the unstriped bronchial muscles and dilate the vessels in the mucosa increasing their permeability. The absorption of histamine would produce a localized eosinophilia and later an increase in the eosinophiles of the blood. Table V shows the analysis of 27 individuals in whom we were able to cultivate these Gram-negative bacilli. Out of the 27 individuals 26 showed an eosinophilia over 5 per cent. The one that did not show eosinophilia had also a leucopenia. We can therefore say when Gram-negative bacilli are found in the sputum we would expect an increase of blood eosinophilia above 5 per cent. The second group of cases are those which we attributed to animal proteins where the product acts on the involuntary muscles of the bronchi and also produces vaso-dilatation of the smaller vessels. These cases are generally considered

Out of 27 cases 26 cases show eosinophilia.

We are now in a position to investigate the value of the eosinophile count in the diagnosis of spasmodic asthma.

Amongst the 150 cases investigated there were only 49 which showed an eosinophile count of less than 5 per cent. The total count varied from 5,000 to 37,000 and out of these 24 individuals showed leucopenia. The majority of these asthmatics showed an eosinophile count over 5 per cent and we had to analyse these cases further. The cases were divided into three groups; group I consisted of 27 individuals in whom we found a Gram-negative bacillus. This organism was first described by Eyre as occurring commonly in cases of asthma. Knott and Oriel showed that certain strains of this

under allergy. Table VI shows the analysis of 44 of these cases giving the total leucocyte count in relation to the number of eosinophiles. Thirty-six out of the 44 individuals showed an increase of over 5 per cent of eosinophiles. In the tropics the function of the liver and the intestinal tract is of great importance. Fourteen out of these patients showed helminthic infection and 10 of these were cured of their asthma by treating them for their helminthic infection. There were in addition 10 cases in which some dysentery organisms were found; thus in three *Entamæba histolytica* was found, and in seven *Bacillus pseudo-carolinus*, *B. morgani*, or *B. meta-dysenterica*. These patients were treated and cured by emetine or

by vaccine treatment. Thus in the tropics the true allergic cases as seen amongst Europeans are rarely observed by us. The third group of

cases. The total count varies from 5,000 to 37,000 and 36 individuals showed an eosinophile count over 5 per cent. Amongst those who did

cases were diagnosed as being secondary to disease or infection of the respiratory tract. Table VII shows an analysis of 79 of these

not show an increase of eosinophiles were four cases of tuberculosis and two cases of bronchiectasis, and there were four patients who

were relieved by being treated for their nasal condition. The majority of the cases in this group showing increased eosinophilia were sensitive to dust.

SPUTUM EOSINOPHILIA

Source of the eosinophile cells in the sputum.

—It is now generally accepted that the eosinophiles in the bronchial wall and the exudate have emigrated from the blood. Bezançon and Bernard (1930) still believe that local eosinophilia is the primary factor and the blood eosinophilia a secondary or associated condition. Heineke and Deutschmann (1906) and Huber and Koessler (1922) think that the deposit of eosinophiles in the lungs during a paroxysm is the cause of their diminution in the circulation during an asthmatic attack.

Value of sputum eosinophilia.—Although eosinophiles may be found in the sputum in diseases other than asthma, Huber and Koessler (*loc. cit.*) believe that the coincidence of sputum and blood eosinophilia in the same individual are a pathognomonic symptom of the asthmatic state. Klewitz (1928) states that although blood eosinophilia may not be noted in every case of asthma, he has never found it absent in the sputum. According to him it occurs both in sensitive and non-sensitive cases. Knott (1930) found that out of 132 cases the sputum was eosinophilic in 85 cases. In our series of 150 cases only 36 had eosinophiles in the sputum. Brown (1927) found that the number of eosinophiles in the sputum of patients ran directly parallel with the percentage of eosinophiles in the blood. Knott (1930) also came to the same conclusion, but we have not been able to confirm this point. Steinberg and Figley (1928) found that but few eosinophiles occurred in the cellular exudate, within the lumen, and in the bronchial wall in bacterial asthma. While in allergic asthma numerous eosinophiles occurred in the cellular exudate, in the lumen and the bronchial wall.

CONCLUSIONS

(1) The percentage of the eosinophiles in the blood is of little value unless the total count is also stated and the eosinophiles are best expressed in the number present rather than in percentages.

(2) If leucopenia is present the number of eosinophiles per cubic millimetre of blood is of little practical use for diagnostic purposes.

(3) An increase of over 5 per cent of the eosinophiles in the blood is an important indication of the presence of some foreign animal protein, or of certain amines which can be derived from the amino-acids of plants or animals, and of the patient being sensitive.

(4) In asthma there are three types of case associated with increased eosinophilia—

(a) Cases where the proteins or amines are derived from the gut or from animal emanations.

(b) Bronchial cases with Gram-negative bacilli in the sputum.

(c) Bronchial cases where there is local sensitiveness of the mucosa to dust, etc.

(5) The presence of eosinophiles in the sputum is not a constant finding in asthma.

DIABETES IN CHILDREN

By J. P. BOSE, M.B., F.C.S. (Lond.)

Diabetes Research Worker, School of Tropical Medicine, Calcutta

Introduction.—The diabetic child is of more than usual interest to those working on this disease, not only because it provides them with pure diabetic lesions unaccompanied and uncomplicated by any degenerative changes due to age, but also because it gives them a better opportunity of following up the effects of treatment. The prognosis in cases of diabetes in children was always thought to be a matter of considerable seriousness in the past, but it is not reasonable to take such a pessimistic view at the present day. There is no doubt that, since the advent of insulin, the outlook in these cases has been much brighter; a great deal may be done to improve the condition of the child which, if it does not prolong his life, will certainly make it more comfortable. This is possible because in a child the regenerative powers are at their highest, and hence under proper care and suitable treatment there is a much greater opportunity for the regeneration of the islet cells of the pancreas. The literature on the subject is replete with evidence that there is a much quicker regeneration of the islands of Langerhans in children than in adults. Boyd (1925) has reported an interesting case

A. Before treatment.

Fig. 1.

B. After 10 weeks of treatment.

A. Before treatment.

Fig. 2.

B. After 13 weeks of treatment.

of diabetes in a boy who recovered but subsequently met with an accidental death. At autopsy, the pancreas was found to be normal with the exception of scattered pyknotic nuclei in some of the island cells. Boyd had observed the presence of a very large number of island areas at the periphery of the pancreas, sometimes twelve or fourteen, in a low-power field. Bensley, in commenting on Boyd's paper, said that these small bulbous islands adjacent to a duct resembled those produced in experimental animals by the regeneration of newly-produced islands.

It may be stated with a certain amount of definiteness that, taken properly in hand, the diabetic child should make considerable improvement within a comparatively short time. Such improvement in the general health and in the proper growth and development of the child takes place quickly if the case is properly managed from the beginning. The improvement is sometimes so marked that the child becomes scarcely recognizable within six weeks from the commencement of the treatment. On the previous page are photographs of two of the author's cases which add support to this statement.

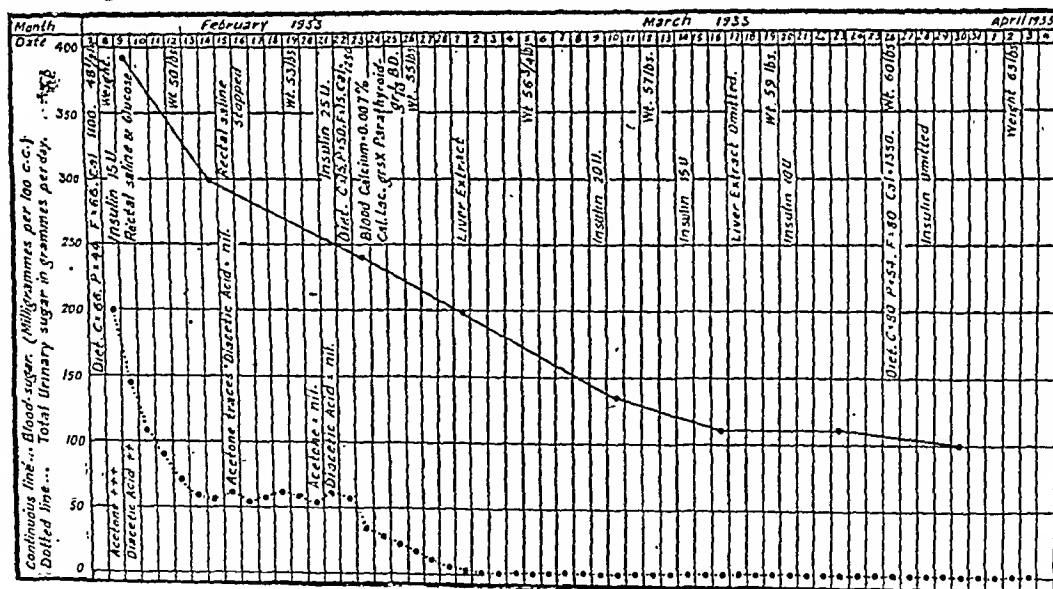

than amongst adults, especially in this country, it is not so very rare as it is usually thought to be. The author had the somewhat unusual experience of having to treat six diabetic children within a space of three months.

Age of onset.—The youngest diabetic child amongst the author's series of cases was a boy aged 1 year and 4 months. The author's experience has been that diabetes is less common in children under 5 years of age. The youngest diabetic child in Joslin's series of cases was a baby 8 months old. Ashby (1923) described the case of a four-months-old diabetic baby with gangrene of the toes. Major and Curran (1925) reported a case with diabetic cataract in a baby 11 months old.

Ætiology.—This is still very obscure. According to many observers, heredity is an important factor. Amongst most of the author's cases, however, heredity could not be traced as playing any important part in the ætiology of the disease. It should be noted here that, unlike diabetes in adults, obesity does not seem to be of any importance as an ætiological factor in diabetes of children. The author is inclined to the opinion that some inherent defect in the endocrine balance of the child, leading to a

Progress of Case (Figure 2). Diabetes Case Sheet.

Name....P.B.H.S. Sex....F. Age....12. Religion....Christian. Physician....Dr. Bose.

While, therefore, the final prognosis in cases of diabetes in children may not be predicted with any amount of certainty, one should not take too gloomy a view of the disease in the present day of insulin treatment. We know that it is possible now to turn a diabetic child from a living skeleton into a robust healthy being, but whether or not this condition can be maintained permanently, only further research can show.

Incidence.—Though there is no doubt that diabetes is much less common amongst children

disturbance in its normal mechanism, is the causative factor in children, though the exact nature of this disturbance is still obscure.

Onset.—In some of the author's cases the onset was sudden and the course was rapid. Two of the cases were diagnosed for the first time when the patient was in a pre-comatose condition—the child having suddenly become ill with an eruptive fever three days previously. In other cases, the onset was slow and insidious, diabetes being wholly unsuspected in the beginning. The usual history in most of these

A. Before treatment.

Fig. 1.

B. After 10 weeks of treatment.

A. Before treatment.

Fig. 2.

B. After 13 weeks of treatment.

is usually taller than other children of the same age.

The following note, as to the special peculiarities of the diabetic children in her charge, was prepared for the author by an observant staff nurse in charge of the children's ward.

(1) Children suffering from diabetes are more intelligent than other children of the same age.

(2) They are very precocious and quick at understanding.

(3) They are inclined to be very cunning and sly in their ways.

(4) Their nature is very sensitive, and great kindness and tact is required in dealing with them.

(5) At times they are depressed, irritable and

rich in fat; at the same time, it should be remembered that the fat content in the diet should not be too low because fat serves as an important carrier of the fat-soluble vitamin A, which is essential to growth. The following table gives the approximate carbohydrate, fat, protein and the caloric requirement of diabetic children in the different periods of their lives. It should, however, be borne in mind that the proportions given below are only average and have to be varied at times according to the nature of the case and according to complications arising or present:—

Age of the child	REQUIREMENTS PER KILOGRAMME OF BODY-WEIGHT			
	Fat	Carbohydrate	Protein	Calories
1-2 years	3 gms.	12 gms.	4 gms.	90
3-5 "	3 "	9 "	4 "	80
6-8 "	3 "	6 "	3 "	60
9-12 "	3 "	3 "	2 "	50
13-16 "	3 "	2 "	2 "	40

hysterical, and need a little firm handling which usually brings them round quickly.

Treatment.—Though the principle underlying the treatment of diabetic children is more or less the same as that of an adult, yet there is a considerable difference in many essential details. For instance, it should always be borne in mind that the food requirements of growing children are proportionately much greater than those of the adult, and a diet which is insufficient in its total caloric value or inadequate as regards the protein ration may cause serious harm. The growing child requires a generous diet which should not only yield the total caloric value needed according to the age of the child but should contain the proper amount of protein to maintain health and vigor, and to promote growth. It should also be borne in mind that children, as a rule, cannot take the same proportion of fat per kilogramme of body-weight as an adult, and they are more liable to develop acidosis.

The essential difference between the dietetic treatment of diabetic children and adults lies in the fact that, whereas in the case of adults the protein requirement under basal conditions is approximately about $\frac{1}{4}$ gramme per kilogramme of body-weight, in the case of diabetic children the protein requirement varies inversely according to the age—i.e., the younger the child, the greater is the protein requirement per kilogramme. The same rule holds good in the case of the carbohydrate requirement, as well as the total caloric requirement. The fat requirement by diabetic children is also essentially different from that by an adult. The ratio of fat to carbohydrate in the diet of the former should be much less than in that of the latter, because diabetic children are more liable to develop ketosis on a diet disproportionately

rich in fat; at the same time, it should be remembered that the fat content in the diet should not be too low because fat serves as an important carrier of the fat-soluble vitamin A, which is essential to growth. The following table gives the approximate carbohydrate, fat, protein and the caloric requirement of diabetic children in the different periods of their lives. It should, however, be borne in mind that the proportions given below are only average and have to be varied at times according to the nature of the case and according to complications arising or present:—

It will be seen from the above table that the caloric requirement per kilogramme of body-weight, as well as the protein and the carbohydrate requirements, increase inversely according to the age—i.e., the younger the child, the greater is the food and the caloric requirement per kilogramme of the body-weight. The fat requirement, however, has been kept at an arbitrary figure, viz, 3 grammes per kilogramme, but the ratio between the fat and carbohydrate in the diet has been altered by proportionately increasing the carbohydrate quota of the diet. For instance, it will be seen that the proportion of fat to carbohydrate in the first two years of life has been kept as low as 1 to 4, instead of the usual proportion, 2.5 to 1, in an adult diet. As the age increases, the proportion of fat has also been increased in relation to the carbohydrates, so that, at the end of the table, a child between the ages of 13 to 16 years gets a proportion of 1.5 to 1, which somewhat approaches the normal adult proportion.

It should also be remembered by the doctor prescribing diets for diabetic children that he must take into consideration the suitability of the food-stuffs according to the age of the child. For instance, the diets of infants under 2 years should mainly consist of milk. For bigger children, eggs, fish, potatoes, bread, butter, vegetables (those without much roughage), etc., should be prescribed.

Insulin therapy.—The principle of the treatment is the same in children as in adults. If the case is an uncomplicated one and of mild nature, and if the blood sugar is not excessively high, the effect of dieting alone should be tried for a few days, in order to see whether this alone has any effect in reducing the blood and urinary sugar, and in improving the general

health of the child. If dietetic treatment, continued for about a week, fails to make much impression, or if the child loses weight, insulin should be commenced. Of course, if the case is of a severe nature, or if there are complications, insulin treatment should be started at once.

Regarding the dosage of insulin, no hard and fast rules can be laid down, but in as much as the dose may vary in individual cases it should be mentioned here that in children the *proportionate* dose of insulin per kilogramme of body-weight is usually higher than in adults, because of the high carbohydrate content of their diet. It should also be remembered that some of the diabetic children require relatively big doses to make their urine sugar-free. One of the author's cases, a child aged 5 years and weighing only 33½ pounds (or approximately 15 kilogrammes), required as much as 30 units of insulin (given in two doses daily) to make his urine sugar-free.

As a general routine, however, it can be laid down that in mild cases, uncontrolled by diet alone, it is best to commence with small doses of, say, 2 to 3 units once or twice daily. In more severe cases with high blood sugar, commence with 5 to 6 units twice daily. As in the case of adults the dose should be increased gradually until the glycosuria disappears and the blood sugar becomes normal.

It must be remembered that in treating cases of diabetes in children, not only must the urine be kept sugar-free and the blood sugar kept within normal limits, but very careful attention must be given to the proper growth and development of the child. The child must grow in height and gain in weight like other normal children. In cases where the urine is made sugar-free but the child does not grow or gain in weight, the diet must be raised and extra doses of insulin given to keep the urine sugar-free; on the other hand, if the gain in weight is abnormally rapid the diet should be cut down and the dose of insulin adjusted accordingly.

To save space, the author has not included any case records in the present paper; those readers, who are interested in the practical details of treatment in such cases, are however referred to a previous paper published by the author (1930).

Prognosis.—It is undoubted that insulin has made a huge difference in the prognosis. It has not only helped to make their lives comfortable, but it has prolonged the lives of these children and made it possible for them to grow and develop almost normally. Joslin's statement with regard to this point is very apposite, he says 'Thirty years ago, when I began treating diabetic children, I counted the days they lived. It is hard to believe, but it is true, that I am now beginning to measure their lives in decades'.

A SCHEMATIC REPRESENTATION OF THE VARIANTS OF CHOLERA VIBRIO PRODUCED UNDER THE INFLUENCE OF BACTERIOPHAGE

By C. L. PASRICHA, M.A., M.B., B.Chir., M.R.C.S., L.R.C.P.
CAPTAIN, I.M.S.

MILITARY ASSISTANT SURGEON A. J. DE MONTE, I.M.D.
and

S. K. GUPTA, M.B., D.T.M.

(From the Bowel Diseases Research Department,
Calcutta School of Tropical Medicine)

IN endemic centres of cholera such as Calcutta and in areas where cholera occurs in epidemic form, vibrios can be isolated not only from cholera cases but also from contacts, healthy individuals, waters, flies and other sources. These vibrios may be divided into two great classes, vibrios that are agglutinable by a specific cholera serum and those that are not agglutinable by this serum. The characters of these two classes of vibrios are given below:—

Class I. *Vibrios agglutinable by cholera serum.*

A. *The vibrio of endemic and epidemic cholera.*—The definitely agglutinating vibrio obtained from undoubted clinical cases of cholera during an epidemic of the disease is universally recognized as the true cholera vibrio. The Japanese authors (Inouye and Kakihara, 1925) have recognized three serological types designated by them as 'V. cholera 1, 11 and 111'. We have evidence, which we shall present in a later publication, that there is more than one serological type of cholera vibrio amongst the agglutinating vibrio isolated by us from clinical cholera cases.

B. *The 'El Tor' vibrio.*—These vibrios were isolated at El Tor from the intestines of pilgrims who had died with dysenteric symptoms and who had shown no clinical symptoms of cholera. There were no cases of cholera in the vicinity. The El Tor vibrios give the serum reactions of true cholera vibrio, but differ from the latter in having marked hæmolytic action. There is considerable difference of opinion as to whether these vibrios are to be regarded as belonging to a distinct species or as true cholera vibrios. Recent investigations have shown that cholera vibrios may develop, lose, or show wide variations in their ability to produce hæmolysins. We have studied the hæmolytic properties of nearly 300 freshly-isolated strains of cholera vibrios and have confirmed these observations. The property of causing lysis of red blood cells

is apparently a latent power of all vibrios and of no absolute value in differentiation of vibrios.

Class II. *Vibrios not agglutinable by cholera specific serum.*

A. *Non-cholera vibrios.*—Vibrios that differ markedly in their properties from the true cholera vibrio and which can be isolated in places where cholera does not exist or has not been for a number of years. This group includes the phosphorescent, chromogenic, non-proteolytic, non-saccharolytic vibrios and other vibrios that have no connection whatsoever with the cholera vibrio. These will not be considered further here.

B. *Atypical cholera vibrios.*—This group includes the vibrios referred to as cholera-like or paracholera vibrios and several of the vibrios that have received specific names. They abound in nature where cholera exists or has recently existed and can be frequently isolated from cholera convalescents, either alone or together with typical cholera vibrios. They are all monoflagellate and motile, they produce indol, liquefy gelatine and give the sugar reactions of the standard cholera vibrio. They differ from the true cholera vibrio in their serological reactions. They themselves do not belong to one serological group. Cross agglutination tests between various atypical vibrios give evidence of a large series of groups which are distinctly differentiated serologically. Greig (1917) found twenty-two serological groups amongst 78 strains of cholera-like vibrios that he examined.

The aetiological significance of the atypical vibrios is still undetermined. It is the want of serological identity of the atypical vibrios with the true cholera vibrio which has led to their being distinguished from the causative organism of the disease. A further difficulty is that as man alone is susceptible to cholera we have no means as yet of determining the presence or absence of virulence in a vibrio. The identity or non-identity of these atypical vibrios with the true cholera vibrio has been the subject of numerous investigations. Although on the subject of the serological variations of vibrios, brought about either by subculture alone or by subjection to other experimental biological

occurring in the specific serological reactions is so deeply rooted in the minds of bacteriologists that many authors emphatically deny either the possibility of the loss of agglutination of a cholera vibrio or that the transformation of a non-agglutinating vibrio to an agglutinating vibrio can ever take place. They hold that such observations are due either to errors in technique or are the results of uncritical investigations and are based on purely theoretical grounds. The nature of the experiments devised to alter the serological characters of a vibrio were such that they did not yield uniform and convincing results. Many investigators, although following the original technique of those who had reported success in bringing about variations in the property of agglutination of a vibrio, found it impossible either to transform a true agglutinable cholera vibrio into an in-agglutinable atypical vibrio or to convert a cholera-like vibrio into a typical agglutinable vibrio. The cause of failure to confirm the results of the variations of agglutinability was due not to faulty technique but, as suggested later by d'Herelle, to the difference in the vibrio itself—the presence or absence of contaminating bacteriophage in the vibrio or the possibility of contamination by bacteriophage in the course of the experiment.

d'Herelle, Malone and Lahiri (1930) were the first to present convincing experimental proof that the property of agglutinability by a specific high-titre serum, which alone distinguishes true cholera vibrio from the so-called cholera-like vibrios, was variable and could be lost. They showed that certain strains of vibrios agglutinable at maximum titre when first isolated became inagglutinable after successive subcultures *in vitro*, and they presented conclusive experimental evidence that such changes are the result of infection of the cholera vibrio by bacteriophage. They summarized the results of the variability of the character 'agglutinability' as follows:—

'Cholera vibrios undergo profound modifications in the intestine of patients the principal stages of which are indicated in the following table, but all intermediate stages are possible because experiments show that the different characters vary independently of one another.

Motility	Morphology	Fermentations	Reduction of nitrates	Hæmolytic power	Agglutination	Virulence

conditions, a mass of literature has accumulated, the belief as to the impossibility of any change

The fact that the various germs possessing characters of such diversity truly constitute real

mutations of the typical cholera vibrio is beyond dispute for similar mutations can be obtained *in vitro* by the action of the bacteriophage'.

We have already shown (Pasricha, de Monte and Gupta, 1931) that the secondary growths that develop after the action of the bacteriophage isolated from a convalescent cholera patient on an agglutinating and phage-sensitive ultra-pure vibrio isolated from the same case are variable in their agglutinability. Non-agglutinating colonies can be isolated from such phage-infected cholera vibrios, whereas in the secondary colonies that develop after the action of laboratory cultures of cholera phage (at that time cholera phage types A, B and C only were known) on freshly isolated cholera vibrio or on laboratory strains, serological mutations could not be so readily obtained. We have repeated these experiments several times and have fully confirmed these findings. With the other types of cholera phage, particularly with types G and H it is comparatively easy to bring about the loss of agglutinability in an agglutinating cholera vibrio. The results of some recent experiments on the effect of bacteriophage on the agglutinability of cholera vibrio are summarized below :—

variant forms of the true cholera vibrio. It becomes, therefore, of the greatest importance to establish whether, under any conditions, the non-agglutinating atypical vibrio can become the agglutinating typical cholera vibrio. d'Herelle throughout his writings and d'Herelle, Malone and Lahiri (1930) stress that when the loss or the modification of a character is the result of a mutation, as for example, the loss of agglutinability of a cholera vibrio by the action of bacteriophage, this character cannot be recovered. The mutation appears to be final and the return to the original form impossible. In discussing the problem of endemicity of cholera they express the opinion that while in epidemic regions degenerated vibrios never recover their virulence, in endemic regions recovery can occur. The unknown factor responsible for the 'regeneration' that occurs in endemic centres of the disease must be of the nature of a living organism present in the waters. They suggest that certain aquatic animals peculiar to Bengal and Indo-China—the endemic centres of cholera—may be concerned; some annelid, crustacean or mollusc in the intestine of which the cholera vibrio can live for a long time and more especially in the intestines of

Serological changes induced in true cholera vibrios after infection with cholera phage (mixed types A, B, C, D, E, F, G, H, J and K)

Titre of agglutination of the strains of vibrios tested	AGGLUTINATION OF SECONDARY GROWTHS WHICH DEVELOP AFTER ACTION OF CHOLERA PHAGE					
	Number of strains tested	Number of strains in which titre of agglutination was unchanged	Number of strains in which titre reduced to half of original	Number of strains in which titre reduced to less than 1/6th of original	Number of strains inagglutinable by cholera serum	Number of strains in which agglutination increased as compared with the original
1 in 6,000 and over ..	29	5	5	5	14	..
1 in 2,000 to 1 in 6,000 ..	16	6	1	1	8	..
1 in 1,000 to 1 in 2,000 ..	5	1	1	3
Less than 1 in 1,000 ..	2	2
TOTAL ..	52	12	6	6	23	5

Of the fifty-two strains of agglutinating cholera vibrio after the action of mixed cholera phage twelve strains show no change in the titre of agglutination, twelve show definite diminution in the property of agglutination and twenty-three, or forty-four per cent, show complete loss of agglutinability. It is interesting to note that out of seven strains of vibrios originally only partially agglutinating the secondary growths of five strains show increased agglutinability.

A number of investigators have recorded the finding of atypical vibrios in waters in association with outbreaks of cholera more particularly towards the end of an epidemic, and that such vibrios are not found in places which have been free from cholera for some years. The experimental evidence of the loss of agglutination by a cholera vibrio under the influence of bacteriophage is so conclusive that it can be reasonably concluded that most, if not all, of the atypical vibrios found in places where cholera exists are

which the avirulent cholera vibrio can become regenerated.

We have already shown (Pasricha, de Monte and Gupta, 1931) that twenty per cent of 355 strains of cholera-like vibrios isolated from waters and man in Calcutta were lysable by ultra-pure races of cholera phage (types B and C). The secondary colonies that develop after the action of cholera bacteriophage on cholera-like vibrios in some experiments are agglutinable by cholera specific serum. They completely

teriophages which we have called cholera-like vibriophages, or vibriophages, in contra-distinction to the pure-line cholera phages. These vibriophages can lyse certain strains of non-

The diagram illustrates the genetic relationships and phage adsorption patterns of various Ag and NaAg strains. At the top, a 'Cholera phage' is shown with a black dot. Below it, various Ag and NaAg strains are listed, including 'EL Tor Type', 'Less Ag', and 'NonAgglutinating'. Lines connect these strains to a series of phage adsorption patterns at the bottom, which are labeled 'Cholera-like Vibriophage'. The diagram illustrates how different Ag and NaAg strains interact with different phages, leading to various adsorption patterns.

Agglutinating "ultra-pure" cholera vibrio (non-hæmolytic).

agglutinating vibrios, and the resulting secondary growths of some vibrios are both agglutinable by cholera serum and lysable by pure-line choleraphages, and are thus indistinguishable

from true cholera vibrios. These experiments have been repeated several times and the previous results confirmed. The results of the examination of fifty-six recently-isolated strains of non-agglutinating vibrios is given below:—

Changes induced in the serological reactions of atypical non-agglutinating vibrios after the action of bacteriophage

Total number of atypical non-agglutinating vibrios examined ..	56
Agglutination reaction unchanged after the action of bacteriophage in ..	32
Number of strains that became agglutinable after the action of cholera-phage ..	11
Number of strains that became agglutinable after the action of vibriophages ..	13
Total number of strains that became agglutinable with cholera serum after the action of bacteriophages ..	24 or 43 per cent.

We have experimental evidence, therefore, that in regions like Calcutta where cholera is endemic there exist bacteriophages under the influence of which, in the laboratory, certain strains of atypical non-agglutinating vibrios can acquire the property of agglutination with cholera specific serum. We have looked for the presence of such bacteriophages in the waters of places where cholera is not endemic. We have examined 150 samples of waters collected at Hardwar and about 100 samples of waters from Kurseong and failed to find such vibriophages. We have not made a sufficiently extensive study of vibrios and phages in non-endemic areas, nor have we made an investigation into the seasonal variations of vibriophages in relation to the epidemic of cholera, to enable us to draw definite conclusions as to the part played by vibriophages in the epidemiology of the disease, but in the laboratory under the influence of a virus disease (cholera-phage) the typical cholera vibrio becomes an harmless saprophytic organism which when once again parasitized by another virus disease (vibriophage) assumes the characteristics which render it indistinguishable from the typical virulent type. That recovery from a chronic disease following infection by another acute disease can take place is not without parallel in medicine. Whether the vibrios regain their virulence or not we have no means of judging. The conclusion is forced upon us that the vibriophages play an important part in the epidemiology of cholera and that they are one of the important factors in bringing about a regeneration of degenerated cholera vibrios.

A schematic representation of the variations undergone by a smooth agglutinating cholera vibrio after the action of bacteriophage is given. We prefer to use the term variants instead of mutants, as the latter term, often loosely

applied, implies irreversible change of characteristics. Doorenbos (1932) recently published a similar diagram but the relationship of the atypical vibrios to the cholera vibrio was not illustrated in the diagram. The variants of cholera vibrio obtained *in vitro* are much more variable in their character than those represented in the diagram which represents the peaks of variability and illustrates the probable relationship of the five great classes of vibrios:—

1. *True cholera vibrio, agglutinable by specific cholera serum.*—In the diagram this vibrio is represented as being non-hæmolytic. We have already said that cholera vibrios show wide variations in their ability to produce hæmolysins and that many strains of cholera vibrio cause rapid lysis of red blood cells. We have shown the cholera vibrio as non-hæmolytic as a contrast to the other vibrios which are frankly hæmolytic.

2. *The hæmolytic agglutinating vibrios—the so-called El Tor vibrios.*—Although we have not isolated vibrios of this type from cholera cases in India, it can be experimentally produced in the laboratory.

3. *Vibrios partially agglutinable by cholera serum.*—This group is a very important one for the study of variants of cholera vibrio.

4. *Vibrios not agglutinable by cholera serum.*—Vibrios of this type can be frequently isolated in nature. They are the aberrant forms of cholera vibrio and do not form an homogeneous serological group. These we referred to as atypical cholera vibrios. The secondary colonies that develop after the action of vibriophages on these vibrios are agglutinable by cholera serum and are indistinguishable from the true cholera vibrio by cross agglutination and absorption tests.

5. *Finally, the 'G' type, small coccid forms which are filter-passers and later develop into vibrios.*—The ætiological significance of these forms is still undetermined.

EXPERIMENTAL STUDIES WITH A SPIRILLUM FOUND IN THE NASAL CAVITY OF SOME LEPERS

By ASSISTANT SURGEON B. M. DAS GUPTA, L.M.P.

Officiating Professor of Protozoology

and

S. N. CHATTERJEE, M.B., D.T.M.

Assistant Research Worker in Leprosy

Calcutta School of Tropical Medicine

WHILE examining the nasal smears for lepra bacilli as a routine diagnostic measure, one of us (S. N. C.) found a spiral organism characterized more or less by its uniformity of shape and size though an occasional individual was larger than others. A few months later a similar organism was found in another case.

A saline emulsion of the scrapings was examined under dark-ground illumination. The organism showed the typical darting movements of a spirillum as distinct from those of a spirochete. Some of the emulsion was injected intraperitoneally into a white mouse which died apparently of sepsis within 48 hours. As the case was lost sight of, no further experiments could be made until in December 1932 we got a third case showing a fairly heavy infection with the spirillum.

This patient has been under our observation for more than 5 months. During this period eleven tame mice have been inoculated with the emulsion of nasal scrapings on different dates. On most of these occasions spirilla could be demonstrated either in stained smears or by examination by dark-ground illumination. Out of these eleven mice nine died apparently of sepsis within 3 days of inoculation. On post-mortem examination performed within two hours of death one showed pneumococci in abundance in the smears of the heart blood. Of the surviving mice one showed spirilla in the blood and the other died 13 days after inoculation; on post-mortem examination of the latter no spirilla were detected in the heart blood or spleen smears.

To eliminate the possibility of spontaneous infections of *S. minus* in the laboratory mice, as reported by Robertson (1930), two young guinea-pigs were injected with the nasal scrapings containing a fair number of spirilla (one in every 5 or 6 microscopic fields).

Both these animals showed scanty infections on the 16th and 23rd days, respectively.

A white mouse subpassaged from one of these guinea-pigs showed a heavy infection (spirillum found in almost every field) as early as the 8th day.

Inoculation of human volunteers

1. Sweeper B, aged 40, was given an injection into the skin of the arm of 0.1 c.cm. of blood of the mouse infected by inoculation of nasal scrapings of case no. III.

Table showing the infectivity of nasal scrapings and blood of Alijan (case III) to different hosts.

After the inoculation he was kept under observation. No sign of inflammation at the site of injection was noticed till the 8th day. On the next day, however, the part became markedly swollen and oedematous. The axillary glands of the corresponding side were enlarged and tender. He complained of severe headache. There was high fever.

The exudate obtained by puncturing the oedematous area showed no spirilla but the blood taken at the height of fever on the 9th and 10th days and injected into mice produced infection in these animals.

On the 3rd day of the fever (or the 12th day of inoculation) an injection of 0.3 gm. novarsenobillon was given which resulted in the fall of temperature, and the local oedema and lymphadenitis subsided in a few days. The temperature has been normal since then.

2. An inmate of the Gobra Leper Asylum volunteered for inoculation. His nasal scrapings were examined before experimental inoculation. There were no spirilla, but a large number of acid-fast bacilli were present.

A few drops of blood from one of the infected guinea-pigs were inoculated into the back of the arm. As there was no evidence of local inflammation or fever till the 11th day, he was given another injection of the blood from a mouse sub-inoculated from the same guinea-pig. On the 8th day from the time of the second injection he developed a typical local lesion, fever and rash on the chest and abdomen. A mouse passaged on the 2nd day of fever was positive for spirilla.

Brief account of the leprosy cases who showed spirillum in the nasal smears

Four such cases have been encountered out of over 3,000 cases examined in the course of about 3 years.

Case I.—Hypopigmented anaesthetic patch on the left side of the abdomen. Gave history of rat bite about 25 years ago, but could not recollect whether he had developed rat-bite fever.

Case II.—Anaesthetic patch on the leg. No history of rat bite.

Case III.—Hypopigmented anæsthetic patch on the left leg. On several occasions the nasal smears were positive for spirilla. The last positive smear was that of 12th May, 1932. He gave no history of rat bite, but complained of irregular fever off and on.

Blood was not infective to mice, but inoculation of nasal scrapings produced infection in mice and guinea-pigs.

Case IV.—Gave no history of rat bite. Showed a fair number of spirilla in the nasal smears.

CANCERUM ORIS IN A MONKEY INFECTED WITH *LEISHMANIA DONOVANI*

By R. O. A. SMITH, D.T.M., I.M.D.

Kala-azar Enquiry, Indian Research Fund Association,
All-India Institute of Hygiene and Public Health,
Calcutta

THE object of this note is to report the occurrence of cancrum oris in a monkey (*Macaca irus*). It is believed that this is the first occasion on which this complication has occurred in an experimental animal infected with *Leishmania donovani*.

The previous history of this monkey is that it had been given a malarial infection in the series of experiments reported by Drs. Napier and Campbell (1932) and that, after the necessary data regarding malaria had been obtained, it had been handed over by Dr. Napier for leishmania infection experiments.

Head of a monkey (*Macaca irus*) showing cancrum oris.

The monkey was injected subcutaneously into one of its limbs with one cubic centimetre of an emulsion of leishmania-infected hamster liver and spleen on 7th June, 1932. A copper wire was immediately tied above the site of

(Continued from previous page)

think of any reason why the spirilla should have a particular liking for nasal mucous membrane.

We are indebted to Lieut.-Col. H. W. Acton, C.I.E., I.M.S., and Dr. E. Muir, M.D., F.R.C.S., for their invaluable help during the investigation.

REFERENCE

inoculation to produce venous congestion of the limb, in the hope that the leishmania would be more readily taken up by the leucocytes in the congested area. This was one of a series of six monkeys which were treated in the same way, and was one of two that became infected with leishmania.

Four months after the inoculation a necrotic process, typically sudden in onset and development, occurred; a swelling was noted one day and the next morning the cheek had ulcerated and sloughed, exposing the bones of the face. The photograph of the head of the animal shows the lesion. The animal was killed, as it would certainly have died within a very short time. A heavy leishmania infection of the spleen and liver was found.

The intensity of infection in experimental monkeys of this species has varied considerably—some being very susceptible and showing quite heavy infections and others not showing any infection at all. In view of the occurrence of this complication, which suggests that in this animal the infection ran a course similar to that occurring in man, it is unfortunate that this was not one of the animals in which an accurate cytological study was made, as it is possible that some changes might have been detected which would have explained the production of an infection of this nature in this particular animal.

'VINCENT'S DISEASE' IN A *MACACA IRUS* MONKEY

By K. V. KRISHNAN, M.B., B.S., M.R.C.P.E.,
D.B. (Lond.), D.Sc.

(From the Kala-Azar Enquiry, Indian Research Fund Association, All-India Institute of Hygiene and Public Health, Calcutta)

CERTAIN necrotic and gangrenous infective processes, such as ulcero-membranous stomatitis, hospital gangrene, noma, and gangrenous laryngitis, in which spirochaetes and fusiform bacilli are found, occur in human beings and go by the name of Vincent's disease. As far as the writer is aware neither these lesions nor these organisms have been recorded in experimental animals. A *Macaca irus* monkey that was being used in kala-azar transmission experiment developed a peculiar inflammatory condition of the palate and nose, characterized by multiple sinuses and a sanguino-purulent fetid discharge. Examination of the pus from the sinuses, both by dark-ground and in stained smears (Giemsa and Fontana), revealed the presence of spirochaetes

and fusiform bacilli. Inoculation of this pus into mice subcutaneously, caused the death of the animals within 24 to 48 hours, after producing extensive local necrosis at the site of inoculation. In the material from the necrosed area in the mice, streptococci and fusiform bacilli were found but not spirochaetes; the internal organs of these animals showed no infection. The history of the monkey in question is as follows:—

It had suffered from an attack of inoculation malaria from 19th December, 1931, to 17th February, 1932, and had proved refractory to subsequent inoculation on 26th July, 1932, and 5th August, 1932; it had received in addition on 6th August, 1932, a small dose (0.1 c.cm.) of *Leishmania donovani* (flagellate culture) subcutaneously. Four months later (8th December, 1932) liver puncture was done on the animal and the material obtained examined for *L. donovani* with negative results. The monkey was being kept under observation when it showed the above-mentioned suppurative condition (first noticed on 7th January, 1933).

The monkey has now had the disease for the past four months, and although the local condition has been slowly and steadily getting worse there has only been very slight constitutional disturbance. Examination of spleen-puncture material from the monkey showed *L. donovani* on 28th April, 1933.

The points of interest about this finding are—

(1) that a gangrenous suppurative process allied to cancrum oris occurs in the course of leishmania infection in *M. irus* monkeys;

(2) that this condition is associated with the presence of fusiform bacilli and spirochaetes.

A photomicrograph of the spirochaetes and fusiform bacilli is given.

THE FILTRABLE PHASE OF THE TUBERCLE BACILLUS

By M. B. SOPARKAR, M.D.

(Officer-in-Charge, Tuberculosis Inquiry, Indian Research Fund Association)

and

SUB-ASSISTANT SURGEON JEMADAR CHANCHAL SINGH DHILON, I.M.D.

(From the Haffkine Institute, Parel, Bombay)

(Preliminary Note.)

A CONSIDERABLE amount of experimental work has been done on this aspect of the life history of the tubercle bacillus during the last ten years and two opposite views are at present held on the question of the filtrability of the tubercle bacillus. One group of observers claim to have proved by experiment the existence of a filtrable form of this bacillus, while another group of workers, having obtained no positive results, are unable to support this claim.

With a view to elucidating this problem experiments on this subject were commenced in 1928. This note deals with some of the main findings of these experiments.

The lines of work adopted consisted of obtaining filtrates of tuberculous material that had been passed through porcelain candles, inoculating them into animals and studying the results of these inoculations.

The material used for filtration consisted of tuberculous sputum (six experiments) and tuberculous tissues of laboratory animals infected with known bovine bacilli (four experiments). Suspensions of the material in saline were filtered through Chamberland L₃ candles, and inoculated subcutaneously into guinea-pigs. In these ten experiments passages were made from guinea-pig to guinea-pig with emulsion of lymph glands and spleens of the previously inoculated animals which were killed at regular intervals and carefully examined for the presence of acid-fast bacilli. These were detected in the whole series in 66 out of 190 animals examined—the positive results being found in different stages of the passage but not uniformly. No typical naked-eye lesions of tuberculosis were, however, detected in any of these animals.

The mere finding in the inoculated guinea-pigs of acid-fast bacilli, however, was not regarded as sufficient evidence of the existence of a filtrable phase, and these were further successfully cultivated and pure growths were obtained in six out of ten experiments. Four of these strains were studied as to their character and all of them were found to differ, both culturally as well as in their pathogenicity, from the strains of bacilli present in the original material used for filtration.

In the first two experiments in which the material used was tuberculous sputum, while the original bacilli possessed characters of the human type, the cultures obtained from the

tissues of animals treated with the filtrates behaved differently—in one instance it resembled the avian type and in the other it was avirulent both for the guinea-pig as well as for the fowl.

In the other two experiments with the tissues of guinea-pigs in which the animals were infected with tubercle bacilli of the bovine type, results with the 'filtrate cultures' were similar to those just described, i.e., these cultures instead of showing characters of the original bovine type behaved like the avian type. In one of these experiments also, the culture derived from an earlier passage animal had not attained the virulence for the fowl acquired by another culture of the same experiment but obtained from a later passage animal—suggesting a gradation. In the rabbit the lesions produced by the latter strain closely resembled those caused by the avian bacillus.

These results seem to indicate not only that there exists a filtrable phase of the tubercle bacillus, but, what is even more interesting, that there is a biological change in the character by which, when suspensions of sputum or of animal tissues containing the human or the bovine type of tubercle bacilli having been passed through a porcelain filter and the filtrates subsequently through bodies of guinea-pigs, the acid-fast bacilli recovered from their tissues are successfully cultivated, these cultures are found no longer to possess the virulence of the original strains for this animal and in some cases to behave like the avian bacillus.

This change in the biological character of the strains isolated from the passage guinea-pigs treated with the filtrates—their avirulence for this animal—may perhaps furnish a possible clue to the finding of atypical tuberculosis by some observers in guinea-pigs inoculated with the filtrates, and also to the negative results of other workers adjudged by the absence in the inoculated animals of signs of classical tuberculosis anticipated when dealing with material containing human or bovine types of bacilli.

THE CONSTANCY OF THE SUGAR-CHLORIDE RELATIONSHIP IN DIABETIC URINES

By K. N. BAGCHI, M.B., B.Sc. (Cal.),
D.T.M. (Cal. & L'pool), F.I.C.

Chemical Analyst to Government, Patna

In going through my old records of the analyses of a large number of samples of diabetic urine examined during the last 16 years, I found that a close relationship appeared to exist between the elimination of chlorides and elimination of sugar in urine. The elimination of sugar appeared to have taken place at the expense of that of other solids, chiefly the chlorides, and it struck me that a suitable formula to express the sugar-chloride relation might be worked out.

The formula I adopted is as follows:—

$$\text{Percentage of sugar} = \frac{G - (Cl \times 10)}{4.4}$$

where G = the last two figures of the specific gravity taken at 15°C.

Cl = percentage of chlorides expressed as NaCl.

For example, if the corrected specific gravity were 1.035 and the chlorides 0.25 per cent, the sugar percentage could be calculated as $\frac{35 - (0.25 \times 10)}{4.4}$ or 7.38 per cent.

It is obvious that the specific gravity should be taken very carefully with a reliable urinometer. All urinometers are standardized at 15°C., that is, they indicate 1,000 in distilled water at the temperature of 15°C.

It is however not necessary to take the specific gravity of the urine at this temperature, if a correction is made. The specific gravity is lowered by 0.001 for each 3 degrees above 15°C., so that if the urine temperature is 27°C., $\frac{27 - 15}{3}$,

or 4, must be added to the urinometer reading to bring it to the true specific gravity.

The estimation of chlorides can be done volumetrically with standard silver nitrate solution and potassium chromate as indicator; this method is sufficiently accurate for the purpose. The standard silver nitrate solution is made by dissolving 29.235 grammes of pure and dry crystals of silver nitrate in a litre of water at 15°C.; one cubic centimetre of this solution is equivalent to 10 milligrammes of sodium chloride. The estimation is made as follows: 10 c.cm. of urine is taken in a flat-bottomed porcelain dish and diluted with about 25 c.cm. of distilled water and then titrated with silver nitrate solution with about 0.5 c.cm. of 10 per cent potassium chromate solution as indicator. Supposing 6 c.cm. of the standard solution were required for the titration, the percentage of chlorides would be 0.6, if 13 c.cm. were required the percentage would be 1.3, and so on. The process is very rapid, takes about two minutes to perform, and is fairly accurate for clinical purposes.

Now with the above data, it is a question of a few seconds to calculate the percentage of sugar. The formula gives the percentage of sugar quite accurately, the difference between the calculated figure and that obtained by actual titration with the Benedict reagent not exceeding 0.5 per cent. It has been observed that if the secretion of urine is profuse and the colour is pale straw, such as is usually met with in advanced cases of glycosuria having large amounts of sugar, the result obtained by this method is particularly accurate; but if the case is complicated with any form of nephritis, in early cases of glycosuria passing small quantities of sugar, in cases with high-coloured urine, and in the presence of excess of urates or phosphates,

the chloride-sugar equilibrium is disturbed and the result is not satisfactory. The best result is obtained in the urine of patients who suspect something wrong with them and come to the doctor for treatment for the first time, but as soon as they are put on a restricted diet, the amount of sugar begins to come down steadily and the result becomes progressively inaccurate and subsequently a condition is reached when the formula becomes unworkable. If the treatment is stopped and the patient indulges in indiscretions in his diet, his condition gets worse

and the chloride-sugar equilibrium is again restored.

The object of publishing this preliminary note is to elicit suggestions for working out a more comprehensive formula which would eliminate the various sources of error caused by urea, urates, phosphates and other interfering substances.

The following is a statement of cases selected from my records to show the normal and complicated cases of glycosuria which have been referred to in the paper :—

Number	Corrected specific gravity	Percentage of chlorides	Percentage of sugar calculated from the formula	Percentage of sugar by actual estimation	Difference between the two results in per cent	REMARKS
1	1.022	0.12	4.72	4.71	+ 0.01	
2	1.029	0.38	5.73	5.80	— 0.07	
3	1.030	0.40	5.90	5.90	Nil	
4	1.016	0.60	2.27	2.35	— 0.08	
5	1.032	0.15	7.0	7.1	— 0.10	
6	1.033	0.45	6.47	6.6	— 0.19	
7	1.026	0.30	5.22	5.30	— 0.08	A trace of albumin and a few granular casts.
8	1.034	0.15	7.40	7.50	— 0.1	
9	1.034	0.26	7.22	6.80	+ 0.42	Excess of phosphates.
10	1.034	0.32	7.0	7.20	— 0.20	
11	1.027	0.4	5.2	4.9	+ 0.3	
12	1.034	0.24	7.18	7.0	+ 0.18	
13	1.038	0.10	8.41	8.50	— 0.09	
14	1.032	0.50	6.10	5.40	+ 0.70	Excess of urates.
15	1.029	0.30	6.0	4.3	+ 1.7	Nephritis with much albumin and casts.
16	1.025	0.10	5.45	2.85	+ 2.60	Abundance of phosphates and urates.

GAVANO

A NEW SPECIFIC FOR AMOEBIC DYSENTERY

By G. H. FITZGERALD, M.R.C.S., L.R.C.P. (Lond.),
D.T.M. & H. (Lond.), D.P.M. (Cantab.)

MAJOR, I.M.S.

Civil Surgeon, Aligarh, U. P.

GAVANO is a new synthetic preparation, prepared by Bayer, and is said to have a specific action on the *Entamoeba histolytica*. No details as to its chemical composition are at present available. It is put up for use both in the form of tablets for oral administration, and in ampoules containing a 0.5 per cent solution for intramuscular injection. I have only used the former, which contain 0.25 grammes of the active product. The course recommended is one to three tablets daily for six days, though this can be increased without ill effects; a second course is given after a week's interval. My practice has been to administer two tablets daily for ten days, the usual dose of castor oil being given at the start.

The makers claim for it that :—

(1) It produces no vomiting.

(2) It is far less toxic than emetine, the therapeutic index tested by injections into cats being 1:3.

(3) There is no cumulative action.

(4) Through its action on the medullary centres it causes a lowering of blood pressure and diminishes CO₂ elimination; this increases vagal activity and results in increased peristalsis of the large intestine.

(5) It has proved to be remarkably effective in the treatment of amoebic dysentery in cats, a condition which is unaffected by emetine.

As I myself had suffered for some years from chronic amoebic dysentery and hepatitis, a condition which necessitated almost constant dosage with stovarsol and occasional courses of emetine to keep in check, I took one course of twenty tablets. This is now over twelve months ago, and I have had no return of the old symptoms and several stool examinations have been completely negative, though these had been positive on numerous previous occasions despite treatment. During the course, I noted a tendency to looseness of the bowels and some dyspnoea, though this was not sufficient to prevent active exercise throughout. It has unfortunately only been possible to give it a limited clinical trial; the following cases, typical of others, may be quoted.

Case I.—Boy aged 18. Had severe amoebic dysentery with about 17 stools daily. Active *Entamoeba histolytica* seen. Placed on Gavano, one tablet twice daily. On the third day the motions were reduced to 4, and traces only of mucus and blood were seen. At the end of seven days the motions were completely normal and two in number only. At the end of ten days he was discharged as cured. The stools were repeatedly examined for three months after and no *Entamoeba histolytica* or cysts were found, and he remained free of symptoms.

Case II.—Man aged 25. Gave a history of passing blood and mucus for the past three months. Active *Entamoeba histolytica* found in the stool. Was given the Gavano course combined with bismuth. After four days the number of motions was greatly reduced, pain had disappeared, and the stools were almost normal in appearance.

He was discharged three weeks after admission, apparently perfectly well, stool examination being negative.

Case III.—Male aged 35. History of passing blood and mucus for 15 days, and pain in the right hypochondrium. Active *Entamoeba histolytica* found. Through a misunderstanding he was given one pill only for seven days, combined with bismuth. Nevertheless, at the end of that period he was passing one motion a day only and all his symptoms had disappeared. He absconded on the eighth day and no further stool examinations were therefore performed.

Case IV.—Male aged 60. Admitted with a large fluctuating swelling the size of a melon in the epigastrie region, which was obviously shortly going to burst.

He was greatly emaciated. The abscess was opened and about three and a half pints of chocolate-coloured pus evacuated. There was very extensive destruction of liver tissue. He was placed on Gavano treatment, and, beyond irrigation of the abscess cavity with saline, nothing else was done. Sixteen days later the discharge had almost entirely ceased, and the wound was healthy and healing rapidly.

Unfortunately at this stage he developed acute lobar pneumonia and died three days later. The ready healing of the wound in a much debilitated subject was most remarkable.

In no case in which I have tried it has Gavano failed to relieve the symptoms of amoebic dysentery, and this without causing the patient any of the discomforts associated with any of the recognized forms of emetine treatment. Nausea is unknown.

To what extent it is capable of permanently eliminating the *Entamoeba histolytica*, it is impossible as yet to say.

My own experiences with it have been so favourable that I feel justified in drawing attention to its possibilities.

My thanks are due to the Haverro Trading Company Ltd. in Calcutta, who kindly supplied me with the drug for this clinical trial.

A Mirror of Hospital Practice

DOUBLE PAPILLOEDEMA FOLLOWING ANTIRABIC INOCULATION: RECOVERY

By H. S. CORMACK, M.C., M.B. (Edin.), D.O. (Oxon.), F.R.C.S.E.

LIEUTENANT-COLONEL, I.M.S.

Ophthalmic Surgeon, General Hospital, Rangoon, and
Lecturer in Ophthalmology, University of Rangoon
and

L. A. P. ANDERSON, M.A., M.D., D.P.H.,
D.T.M. & H. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Director, Pasteur Institute of Burma, Rangoon

On the 6th April, 1932, a healthy-looking Anglo-Indian lady, aged 31, came to see one of us (H. S. C.) with the following history:—

On about the 27th March, 1932, the sight of her right eye began to go dim and three days later her left eye began to go dim also.

When first seen, on 6th April, her sight was: Right eye = 6/36 and Left eye = No perception of light.

Both pupils semidilated: Right pupil contracted to light but did not remain contracted. There was also a consensual contraction of left pupil and it also was not maintained.

The left pupil was quite inactive to direct light and there was no consensual reaction. The ophthalmoscope showed a typical papilloedema of both discs. A swelling of between $1\frac{1}{2}$ to 2 dioptries in each. No hæmorrhages or exudates. Apart from her very natural mental distress she was not ill.

She was admitted to the Rangoon General Hospital, and the first physician was asked to examine her with the object of finding a cause for the condition. His results were uniformly negative. Her other cranial

nerves were normal. She was put on mercury, potassium iodide and strychnine injections.

Towards the end of the second week of her stay in hospital she said the sight of her left eye was coming back. One was doubtful of this till it was noticed that the pupil of that eye was beginning to react to direct light.

From this time onwards the improvement in her sight in each eye continued and she was discharged at the end of two months with full vision (6/5) and full fields in her right eye. Her left eye was the same except that she complained of a faint 'shimmering haze' in front of this eye. This was due to a small centro-caecal scotoma which shows up on a Bjerrum's screen with a 2 mm. test object (white) at one metre. Her distant vision in this eye was '6/5 three letters' and she read Jaeger No. 1 correctly but much more slowly than she did with her right eye.

Up to this time we were unable to find any cause for the condition and were quite in the dark as to the ætiology. The mercury treatment was stopped after a week as her Wassermann reaction was negative.

Some weeks after her discharge from hospital it was discovered by mere chance that she had recently undergone a course of antirabic treatment at the Pasteur Institute, Rangoon, and that her sight became affected about five or six days after her last antirabic injection. She had not connected her eye trouble with the antirabic inoculations and had therefore not reported it to the Pasteur Institute, nor mentioned the inoculations at the hospital.

DETAILS OF ANTIRABIC TREATMENT

The patient, a healthy, normal woman, was bitten by a dog, which was certified rabid, on 3rd March, 1932. She reported at the Pasteur Institute, Rangoon, on 5th March, two days after the injury.

There was one deep bite on the arm, inflicted through the bare skin; the wound had been cauterized with pure carbolic acid.

She was given Class III treatment, i.e., 5 c.c.m. of a 5 per cent carbolized sheep vaccine, daily for 14 days, receiving in all 3.5 grammes killed sheep fixed virus. She attended regularly from 5th March for her treatment, which was completed on 18th March, 1932.

No untoward symptoms whatever were observed during the course of treatment.

A few days ago (4th April, 1933) her eyes were examined again, that is, just over one year since the disease started. Except for the small scotoma her eyes are normal. There is no peripheral contraction of the fields. Her optic discs are of a healthy pink colour; edges distinct; good physiological cups with cribriform plate well shown at the bottom of them. The blood vessels are normal. At no time were there any exudates or hæmorrhages. The latter were looked for even with a red-free light. Right vision = 6/5 and J 1; left vision = 6/5 three letters and J 1 slowly but accurately.

DISCUSSION

The question as to whether this case is an example of the so-called 'post-inoculation paralysis' is a very interesting one. As is well known, antirabic inoculation is occasionally followed by disorders of the nervous system which, though their ætiology is still undetermined, have undoubtedly a causal connection with the inoculation.

These nervous disorders present a great diversity of form, varying from slight weakness of one or both legs, or simple facial paralysis in the mildest cases, through a more severe condition with complete paraplegia, to a very grave and usually fatal ascending paralysis of the Landry type.

Such are the forms in which these disorders are usually manifested, but affections of almost every part of the nervous system, including the various cranial nerves, have been reported.

A careful search of all available literature has failed to bring to light any case similar to this one, in which the part of the nervous system affected was the optic nerves themselves, but there seems no reason to suppose that this part of the nervous system should necessarily be exempt from attack by a disease whose incidence on that system is so widespread.

In a personal communication to one of us, Lieutenant-Colonel H. E. Shortt, I.M.S., Director, Pasteur Institute of India, Kasauli, states that he recollected seeing a report in which optic neuritis, or at any rate blindness, had been observed in animals after antirabic treatment; but he, too, was unable to find the actual reference.

The following points are in favour of this case being one of post-inoculation paralysis.

First, the fact that no other cause for the condition could be discovered, at a time when nothing was known as to her previous antirabic treatment.

Secondly, the incubation period—about 20 days from the first treatment—corresponds with that observed in cases of post-inoculation paralysis, practically all, if not all, of which occur within the first thirty days, reckoning from the date of the first treatment.

Thirdly, her remarkably complete recovery from such a severe condition. Except in the gravest cases and those of the Landry type, the prognosis of post-inoculation paralysis is good, and the tendency is to complete recovery after a longer or shorter period. In this case, serious as the damage appeared to be, both eyes had returned practically to normal in little more than two months.

A PEDUNCULATE LIPOMA

By B. U. PUROHIT, L.C.P. & S. (Bom.)

Assistant Medical Officer, Goodfellow Hospital, Palanpur (N. G.)

THE patient, a Hindu male aged about fifty, came to hospital to seek relief from a large ulcerating tumour in the right gluteal region.

History.—The tumour was first noticed in 1901 as a soft cushion-like pad causing no pain or inconvenience in its early stages. It gradually increased in size until it reached its present dimensions (*see illustration*). It will be noted that it is pedunculated. During the last three or four years it has practically prevented his walking and more recently it has become ulcerated; this induced the patient to come to hospital.

Under infiltration anesthesia with percaïn and adrenalin the tumour was successfully removed.

It was found to be a multi-lobular lipoma with no secondary changes, and it weighed thirty-seven ounces. The case is of interest on account of the unusual size of the tumour and its long pedicle.

AN IRON RING ON THE PENIS

By S. N. CHATTERJEE, L.M.S.*

Palganj Dispensary, Hazaribagh District

A boy, aged about 18 years, was brought to me with the following history:—

To relieve a pain in the penis he placed thereon an iron ring about three-quarters of an inch in diameter and three-quarters of an inch in breadth, which he pushed right down to the base of the organ.

I saw him some hours later and the penis was intensely swollen being about eight inches in length and four and a half inches in circumference; he had complete retention of urine for the relief of which it was not possible to pass a catheter. Eventually after cautiously cutting through the ring with a blacksmith's saw, which operation took about three hours, I was able to expand the ring and remove it, and the patient experienced instant relief.

Indian Medical Gazette

AUGUST

THE CENSUS AND THE MEDICAL PROFESSION IN BENGAL

UNEMPLOYMENT in every walk of life and in every part of the world has been a problem ever since the termination of the great war, and during the last few years of world-wide depression the seriousness of this problem has been markedly aggravated. In India the ryot, even if he has temporarily abandoned his village and sought employment in the town, can return to his home, take up his share in the work of cultivation of the land, and thereby ensure his modest daily requirements. In the Bengal village at any rate actual starvation is almost unknown and, though undernourishment is the rule, it is the nature of the food rather than the quantity that is at fault, so that amongst this class the unemployment problem is not so real. But with the educated classes the state of affairs is very different. Naturally after spending money on education they are not prepared to return to the village and do work which they have learnt to consider the duty of menials, consequently in Bengal, and in many other parts of India, the proportion of this class on the unemployed list is enormous; one has only to advertise for a clerk on Rs. 50 a month to get two or three hundred applicants. The 'learned' professions have suffered with the rest and nowhere is this state of overcrowding more apparent than in the medical profession in the large cities in India.

The population of Bengal in 1921 was 44,599,233, whereas in 1931 there were 51,087,338 persons in the province; this means that during the last intercensal decade there has been a 7.3 per cent increase in the general population. In the 1921 census, the medical profession—including registered and unregistered practitioners and dentists—totalled 43,172, and in 1931 the same group contained 53,424 persons—an increase of 23.7 per cent. Thus the percentage increase in the medical profession is three times that of the increase in the total population, or in other words during this ten-year period the number of individuals per practitioner has fallen from 1,102.5 in 1921 to 956 in 1931.

The census returns for the British Isles for 1931 are not yet available, so for purposes of comparison we will use the figures for the 1921 census of England and Wales; at this time there were 1,564 individuals per practitioner in these two sections of the British Isles. It is true that the English figures do not include unregistered practitioners, whereas those of

Bengal do, but the number of such persons engaged in whole-time work in England is so small that their influence on the total would probably be unappreciable. In Bengal, however, 42 per cent of the persons engaged in whole-time work connected with the healing art are unregistered; nevertheless, they must be included in the calculations, because the influence of these unregistered practitioners on the earnings of the registered practitioners is very considerable, and is often a cause of complaint from the latter. If we exclude the unregistered class, the number of persons in the province per registered practitioner is 1,649.*

For many years the cry in Bengal has been for more medical men for the country districts and to meet this demand small medical schools have been opened in the division-headquarters towns in the province. The position has now been reached when on paper there is an adequate supply of medical men for the whole population, but the fact still remains that in practically every country district in Bengal the provision of medical personnel for the population is far below the ideal. What is the explanation for this anomalous state of affairs, unemployment amongst the medical profession on the one hand and insufficient medical attention for the majority of the population on the other? One of the obvious causes is uneven distribution of medical men in the province.

There is a tendency in Bengal just as in other provinces and other countries for medical men to gravitate to the large population centres. It is not difficult to see the reason for this. The student sees that in the town where he has been educated there are opportunities for a higher grade of practice which his training had taught him to appreciate; he realizes that those pleasant aids to diagnosis, such as x-rays and even the microscope, will probably be for ever out of his reach in a country practice; if he is ambitious he also sees that it is only in the towns that big reputations—and incidentally big fortunes—are to be made; and even if he has few ambitions and is prepared to face

*Since writing this we have received the Bengal Annual Medical List for 1933; this list contains 8,889 names of which 540 have been added, or restored, during the year 1932. There may be a certain number of practitioners registered in other provinces who, though practising in Bengal, have not registered; on the other hand in view of the fact that in the present list we recognize the names of many who have long since left Bengal, and some who have left this world altogether, and that during the year no names were removed 'on evidence of death', the figure is likely to be greater, and not less, than the number of registered practitioners actually practising in the province at the beginning of the year. The discrepancy is hard to explain except on the grounds that the census figures are wrong; in addition to the 42 per cent who admit to being unregistered, there must be another 42 per cent or so who, though unregistered, are posing as registered practitioners. If this is the case our argument regarding the plentiful supply of registered practitioners is weakened but that regarding the bad distribution of the profession in Bengal is strengthened considerably.

medical practice in its simplest form and to treat his patients symptomatically and empirically, he is still faced with the problem of earning his living, which, if he is prepared to bury himself in a country district, where his services are really needed, he may have considerable difficulty in doing. This tendency on the part of the medical profession to congregate in large towns is thus governed by either laudable ambitions or sound common sense; the young doctor feels that it is better to risk starvation in the town than to court it with certainty in the country; one could not, even if one wished, legislate against ambition; the only alternative is to make it worth the while of the medical man to settle in the country. This is a problem which we do not propose to discuss here as it would lead into too many by-paths, as for example into the question of subsidies, and the limitation of the activities of unqualified practitioners, many of whom are uneducated, have a lower standard of living and are governed by no ethical rules, and are a continual thorn in the side of the registered practitioner, especially in country districts, but its solution is one of the most urgent medical needs of the present day.

Another aspect of the problem is also brought out in the recent census. Amongst what might be termed the accessory services to the medical profession (nurses, dispensers, hospital orderlies, masseurs, etc.) the numbers in Bengal have only increased from 14,066 in 1921 to 14,339 in 1932, that is to say by only 1.9 per cent. These figures show that for every 3.7 practitioners in Bengal only one of the assistant group is available.

Though the medical man is taught the rudiments of dispensing and though his knowledge of the action of drugs should ensure that he does not poison his patients, he has not been trained to be an expert dispenser, and if circumstances make it necessary for him to dispense his own prescriptions he will do it less expertly and much more slowly than the trained dispenser. The same is true of nursing; few doctors, even women doctors, make good nurses, and therefore when they are compelled to do work which is really that of a nurse, they are not only wasting their time but they are failing to give the patient the most expert assistance. Thus, this shortage of trained nurses and dispensers, to take the two most important members of this 'accessory' class, is a very serious handicap to the medical profession in this country—it is a state of affairs that exists not only in Bengal but everywhere in India—and it must lead to a very serious waste of time of the practitioner in doing things for which he has not been trained and which could be done by less-expensively-educated persons; as a consequence both the quality and the quantity of his legitimate work will naturally suffer.

In England and Wales a very different state of affairs exists; the 1921 census shows that

for each medical practitioner there were just over five of the assistant class, a complete reversal of the proportions. The great majority of these consists of female nurses. In India women have not yet taken up nursing in the way they have done in England and other western countries, but there is no reason why this gap should not be filled meanwhile, to a much greater extent than it is at present, by male nurses or dressers.

There are thus two lessons to be learned from a study of the census report with regard to the provision of medical relief for the people of Bengal, namely that it is not more medical men but a better distribution of the present members of the profession that is required, and that the value of the work of the qualified doctor could be very considerably enhanced if more trained members of the 'accessory' services were available.

These observations were called forth by a study of the *Bengal* census report; in many parts of India there is a real shortage of medical men per head of population, but the remarks regarding the shortage amongst the accessory services will hold good throughout the whole of the peninsula.

Special Article

A NOTE ON PROFESSOR NICOLLE'S VIEWS ON THE TYPHUS AND RELAPSING FEVERS

By SIR JOHN MEGAW, K.C.I.E.

MAJOR-GENERAL, I.M.S.

Director-General, Indian Medical Service, New Delhi

PROFESSOR CHARLES NICOLLE has an interesting note in the *Bulletin de l'Institut Pasteur* of October 1932 on the differential diagnosis of the various forms of typhus fevers which are of interest to the French doctors in Europe, Africa and the Middle East. He leaves out of account the Rocky Mountain and Japanese River fevers which do not occur in Europe and Africa and apart from them he recognizes three types of typhus, (1) *old-world typhus* conveyed by lice, (2) *benign typhus* conveyed by fleas, and (3) *fièvre boutonneuse of Tunis* or *macular fever* conveyed by ticks.

Typical cases of these forms of the diseases can be distinguished with ease, but there is no diagnostic feature which is of universal application. In old-world typhus the severity, the scantiness of the rash, the prolonged convalescence and the epidemic nature of the disease are usual features. Benign typhus is usually mild and endemic while the tick-borne macular fever is always endemic. From the laboratory point of view benign typhus and old-world

typhus have viruses which are mutually protective, whereas neither protects against the macular fever. An essential difference is that lice can be infected by the two former kinds of typhus but not by the virus of macular fever which is conveyed by a tick (*Rhipicephalus sanguineus*). The Weil-Felix response is also much less pronounced in the case of the macular fever. The rat is readily inoculable with benign typhus and constitutes the animal reservoir of the disease whereas it is practically immune to old-world typhus whose reservoir is the human being.

Nicolle, therefore, proposes to call these two diseases 'historical typhus' and 'murine typhus'. The virus of each of these two forms of typhus is pathogenic for the louse while that of the tick-borne macular fever is not; but whereas the virus of murine typhus is rapidly lethal to lice, some of them dying as early as

The confusion in nomenclature of the fevers of the typhus group is not likely to be lessened by the new proposal of Nicolle. My suggestion to employ the name of the insect vector has obvious practical advantages; difficulty only arises when there is no evidence as to which vector is concerned and in this case we have to fall back on the term 'typhus group fever of unknown vector'. Nicolle's suggestion to employ the name of the animal which is the reservoir of the disease is quite logical, provided that there is only one animal concerned in connection with each fever and also that we know which animal is responsible. Now that the flea has been definitely incriminated as the vector of one kind of fever of the typhus group in some French ports and in the eastern Mediterranean, it is necessary to extend my former classification, based on insect vectors, as follows:—

Fevers of the typhus group

	Louse typhus	Tick typhus	Mite typhus	Flea typhus	Typhus of unknown vector
Synonyms	(Typhus fever, classical typhus, historical typhus, etc.).	(Rocky Mountain fever, Indian tick typhus, fièvre boutonneuse, etc.).	(Tsumugamushi, Japanese River fever, etc.).	(Benign typhus, murine typhus, etc.).	

the third day, the virus of historical typhus is much less lethal to these insects. According to Nicolle this difference shows that the adaptation of murine typhus to lice is of more recent date than that of historical typhus, and on the other hand neither of these two viruses is lethal to fleas although both of them infect these insects and the infection persists for a long time.

This note of Nicolle is of special interest to workers in India. It may be pointed out that the tick-borne macular fever corresponds very closely in all essential points with the disease to which the writer has given the provisional name of *tick typhus*, and it is probably the same disease.

Of the other classifications which have been suggested the best is probably 'epidemic typhus' and 'endemic typhus' but as both tick typhus and mite typhus are endemic and as louse typhus is not always epidemic this classification has serious shortcomings. In fact it is a case of choosing between provisional classifications rather than of suggesting one which has a permanent scientific basis. So far as India is concerned the only vectors regarding which there is clear evidence are lice and ticks, but it is necessary to keep an open mind as to the possibility of mites, fleas or other vectors being concerned in the conveyance of fevers of the typhus group in India.

Summary of laboratory diagnostic features according to Nicolle

	Old-world typhus. (Louse typhus)	Benign typhus. (Flea typhus)	Fièvre boutonneuse of Tunis or macular fever. (Tick typhus)
Insect vector	Louse	Flea	Tick
Epidemicity	Usually epidemic	Usually endemic	Always endemic.
Specificity of virus	Protects against benign typhus but not against macular fever.	Protects against old-world typhus but not against macular fever.	Does not protect against the other two.
Infectivity to lice	Infective	Infective	Non-infective.
Lethality to lice	Moderately lethal	Highly lethal	Non-lethal.
Weil-Felix reaction	Strongly positive	Strongly positive	Variably positive, often negative.
Infectivity to fleas	Infective	Infective	Non-infective.
Rat inoculability	Slight	Pronounced	Doubtful, usually negative.

Relapsing fever group

Nicolle discusses the origin of the virus of the two chief forms of relapsing fever. One of these he calls *world-wide relapsing fever* and the other *tick relapsing fever*. There are a great many types of tick relapsing fever and Nicolle confines himself to the type which occurs in North Africa which is conveyed by *Ornithodoros erraticus*. He deals with the clinical differences between louse relapsing fever and tick relapsing fever and points out that the number of spirochaetes in the blood is very much greater in

louse relapsing fever than in the form which is carried by ticks. The animal *par excellence* which can be used to distinguish the two forms is the guinea-pig; this animal is refractory to the virus of louse relapsing fever, whereas it responds readily to inoculation by the virus of tick relapsing fever, which causes a pronounced attack of the disease with relapses accompanied by the presence of numerous spirochaetes in the blood. Here again the provisional classification into 'tick relapsing fever' and 'louse relapsing fever' appears to be the most convenient.

D.P.H. COURSE AT THE ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH, CALCUTTA

The courses of instruction for the D.P.H. examination will commence from the 15th October, 1933, at the above Institute, in collaboration with the School of Tropical Medicine, Calcutta.

Applications for admission should be made by the 31st August next, to the Director, All-India Institute of Hygiene and Public Health, 21, Central Avenue, Calcutta.

'MEDICAL PRESS AND CIRCULAR'

THERE are very few numbers of this *Gazette* in which there is no extract from the *Medical Press and Circular* in the Current Topics section, so that our readers scarcely require an introduction to this essentially practitioners' journal. It is a weekly publication, and it must be a very rare occurrence for a practitioner not to find something in the number that is of immediate practical importance to him. The policy of the journal is conservative in that they do not allow writers with newly-discovered but ill-tested forms of treatment to contribute, but when any new discovery is established the editors always manage to get an article from some sound authority on the subject. Dr. Harry Campbell who has been editor for a number of years has just retired and though we miss his genial editorial notes—especially his weekly attack on the rash motor-car driver—we see no signs of any alteration in policy or any falling off in the interest of the editorial commentaries.

At the beginning of this year this journal commenced to issue a series of quarterly supplements; each is to be on some subject of special interest to the general practitioner. The last of these supplements is on common skin diseases; one of the articles has been extracted for our Current Topics section and will appear in our next number. The supplement is printed on special art paper, and the illustrations are numerous and well reproduced. The whole will form a very useful addition to the practitioner's library, as these supplements are certainly worth keeping and binding.

BENGAL COUNCIL OF MEDICAL REGISTRATION

The following extracts are taken from the minutes of the meeting of the Bengal Council of Medical Registration held on 8th February, 1933, forwarded to us by the Registrar under letter dated 28th June, 1933:—

The government resolution on the appointment of Dr. B. N. Ghosh, L.M.S., F.R.F.P. & S., L.M., and Dr. T. Ahmed, M.A., D.O.M.S., F.R.C.S., representatives of the Bengal Council of Medical Registration and the Governing Body of the State Medical Faculty of Bengal, as

members of the Bengal Sanitary Board for one year with effect from 22nd December, 1932, was recorded.

The government notification regarding election of Major B. H. Singh, I.M.S., in place of Dr. K. M. Basu under clause (c) of section 4 of the Bengal Medical Act, 1914, was recorded.

Government expressed their inability to accede to the recommendation of this Council that medical certificates granted by registered medical practitioners to gazetted officers applying for leave be accepted and it was decided that government be requested to reconsider their decision.

On an application from the registrar, Rangoon University, it was decided that a report be made to the local government under section 18 recommending that the M.B., B.S. degree of the Rangoon University be recognized as registrable in Bengal.

Reports on the inspection of the undermentioned medical schools were considered:—Calcutta Medical School, National Medical Institute, Jackson Medical School, Jalpaiguri, and Chittagong Medical School. It was decided to recognize the Chittagong Medical School and to recognize temporarily for one year the Jackson Medical School, as institutions qualified to train and send up candidates for the Licentiate Examination up to the Final standard.

The following gentlemen were appointed members of a Standing Committee to inspect medical schools:—

Lieut.-Col. A. D. Stewart, M.B., Ch.B., D.P.H., I.M.S.

Sir Kedarnath Das, Kt., C.I.E., M.D.

Dr. S. K. Mukherjee, D.O., D.O.M.S., F.R.C.S.

Mr. Mrigendralal Mitra, F.R.C.S.

Dr. A. D. Mukherjee, L.M.F.

On the motion of Dr. S. C. Sen Gupta, M.B., Ch.B., F.R.C.S., M.D., it was decided that the schools be allowed to take in 10 per cent in excess of the normal permissible number of admissions in the first year class.

The undermentioned gentlemen were appointed members of the Penal and Ethical Cases Committee for the year 1933:—

Sir Kedarnath Das, Kt., C.I.E., M.D.

Lieut.-Col. T. C. Boyd, F.R.C.S., D.P.H., I.M.S.

Dr. J. N. Maitra, M.B.

Dr. Pramathanath Nandi, M.D.

Dr. A. D. Mukherjee, L.M.F.

FIFTY YEARS AGO

(From the *Indian Medical Gazette* of August 1883, Vol. XVIII, pp. 209, 210, 211, 225, 226 and 227)

On the radical cure of hernia by Spanton's method

By ARTHUR NEVE, L.R.C.P. & S. (Edin.)

Mission Hospital, Kashmir

A CASUAL glance through recent medical literature shows the attention which is being devoted to the subject of hernia. It is only within the last few years that

the radical cure of hernia has come within the range of practical surgery. In this country, where there is difficulty in obtaining suitable appliances, and where surgical help is not always immediately available, a radical cure becomes of primary importance. In England it will likely long remain the rule that only cases in which a truss does not yield efficient support, or those liable to recurrent attacks of strangulation, will be submitted to operative measures. But in India, if it be possible to operate without danger and with fair chance of success, it is desirable to do so in almost every case that presents itself.

What are the forms from which we have to select? 'The older methods were', I quote from Birkett, 'castration; cauterization of the orifice and neck of the sac; ligature applied round the neck; incision of the sac and subsequent healing of the wound by granulation; excision, suture and scarification of the sac; detachment of the sac from its connections and returning it into the abdomen; immediate and forcible compression of the sac by a bandage or truss, cold douche; stimulating injections, especially tincture of iodine'.

The methods were barbarous. They were all faulty in conception and futile in practice; often, too, highly dangerous. None of them were aimed at the real seat of the disease—the patent inguinal canal.

But my own experience during the past year with Spanton's screw points to a method as safe as it is simple, and affording good results.

Nine cases have been thus operated upon; in most cases the patient was as soon as seen put upon the table, and having been anesthetized, the instrument was introduced.

I never use the spray while thus operating. The performance of the operation, including the incision of the skin, partial separation of the sac, introduction of the indicating finger, and insertion of the screw, scarcely occupies two minutes.

The ring usually admits of two points on either side being approximated, by two complete turns of the instrument. As this is done the pillars are felt not merely to be brought in contact but to be rolled over one another and the finger is squeezed out of the canal. One or two more turns of the screw being given, the point of the instrument is brought out of the scrotal wound. In all these steps Mr. Spanton's instructions are closely followed. A strip of lint soaked in carbolic oil is wound round the ends of the instrument: this is the only dressing.

By the third day there is always some hardness and swelling over the track of the screw and a few drops of pus exude. The instrument is left *in situ* till usually the seventh day, sometimes longer. At this time it can be withdrawn with ease and with little pain.

The wounds are then suitably dressed, and for a few days discharge a few drops of pus; but the sinus quickly heals, sometimes in five or six days. The swelling gradually lessens, but the hardness remains and conveys an impression of great security.

Medical women for India

The movement, which we discussed at some length in our issue for July 1882, has assumed a practical shape, and is about to enter upon the phase of experiment. The somewhat visionary proposal to organize a medical service of lady doctors to meet a demand which has not been shown to exist, and fulfil a purpose the reality and success of which are doubtful, has been laid aside and wiser and more moderate counsels now prevail. It is unfortunate that philanthropy is so often associated with want of common

sense, and the divorce between these attributes has been very manifest in much that has been written on this subject. Arithmetic is often made to supply the place of investigation in India, and it has been caused to do duty in this question in the following fashion. The population of India is 250 millions, the female population must therefore be over 100 millions. Allow a lady doctor to every 100,000—a very moderate proportion—and the number required for India would be 1,000 at the very least.

This was the view which a majority of the Council of the Calcutta Medical College took when the question of the medical education of Indian females was recently referred to them. They considered that the requirements of the country pointed rather to the provision of educated midwives and nurses than of full-blown lady doctors, that these requirements were being very imperfectly fulfilled, and that the social experiment (for even in Europe and America the matter is still in an experimental stage), of educating women for the medical profession would be more safely conducted by gradually developing existing arrangements, of whose necessity and propriety there cannot exist a doubt, than by proceeding *per saltum* to the extreme phase of the undertaking. The Government of Bengal has, however, assumed the responsibility of throwing open the Medical College and hospital to females, and one young lady, a B.A. of the Calcutta University, has availed herself of the privilege, and is now enrolled as a regular student of the College, and diligently attending lectures and pursuing her studies. In Madras, at the instigation of Surgeon-General E. Balfour, lady students were admitted in 1875 into the Medical College under special rules.

Commercial Aspects of Bacteriophage Therapy

(From the *Journal of the American Medical Association*, 20th May, 1933, Vol. C, No. 20, p. 1603)

THE premature commercial exploitation of 'bacteriophage' has no doubt induced expenditure of considerable sums for therapeutically inert preparations of bacteriophage-lysed bacterial filtrates. Laboratory scientists suggested the subtle and misleading name 'bacteriophage'. True, certain bacterial filtrates introduced into a limited volume of fluid culture medium will in many cases cause the suspended bacteria to die. The dead bacteria disintegrate. After disintegration, a hundred times the original lytic titre is demonstrable in the culture medium, together with numerous other autolytic products.

Ignoring possible enzymes, hormones, genes and other growth factors, imagination pictured this lysis as the result of a hypothetical bacteria-digesting virus. A specifically active lytic agent of this character would logically not affect other factors in the animal body. It was argued that it might penetrate to the remotest corner of infected tissues in search of its specific diet. The well-known fact that test-tube lysis does not take place in the presence of gelatin, egg white or numerous other colloids was disregarded. The well-confirmed evidence that similar inactivations take place in the presence of mucus, fibrin, pus, blood serum, erythrocytes, fixed tissue cells and certain urinary crystalloids was also ignored by commercial interests, in spite of the fact that voluminous data have been published during the last twelve years.

The commercially-promoted reading matter also carefully evaded references to the well-confirmed evidence that limitation of volume is a necessary factor in test-tube lysis. In other words, 'bacteriophage' has

no appreciable injurious effects on homologous bacteria until the extrabacterial concentration of bacteriophage is raised to a certain critical level. Publication of this fact might have suggested to prospective purchasers that the necessary critical concentration could rarely be reached or maintained in any tissue supplied with a capillary circulation, or in any urinary or cerebro-spinal space with its constant lavage with new fluid.

Under the numerous test-tube conditions in which lysis does not occur, 'mutation' or 'adaptations' of the exposed bacteria take place, with the production of bacteriophage-resistant strains. These strains cannot be lysed even under most favourable test-tube conditions. The commercial literature failed to announce that 90 per cent of all typhoid bacilli freshly isolated from typhoid stool or typhoid blood are bacteriophage-insusceptible variants. One also seeks in vain for any reference to bacteriophage anaphylaxis or to anti-therapeutic 'negative phases', the well-known dangers and contraindications with certain other protein mixtures or bacterial vaccines.

Competent investigators who have made impartial and conscientious efforts to determine the clinical value, limitations and dangers of the Twort transmissible lysin marvel at the policy of suppression of scientific fact in the promotion of bacteriophage preparations. If data suggesting limitations and dangers had been suitably set forth in advertising prospectuses, clinical trials might have been limited to certain well-defined pathologic conditions leading eventually to official endorsement, whereas the Council on Pharmacy and Chemistry has not yet accepted such preparations. Moreover, there is a rapidly growing resentment and distrust of the whole bacteriophage promotion, which certainly will delay final clinical evaluation.

Premature exploitation of the Twort lysin is by no means an isolated example of this short-sighted policy. The opsonic index was successfully sold to the medical profession, long before its technical errors were assayed, before any critical test was made of the assumed quantitative parallelism between specific opsonic index and specific immunity. Perhaps a million doses of leukocytic extract were injected before any quantitative tests were attempted to prove that such injection causes anything more than a borderline reaction of negligible therapeutic value. 'Anti-cold vaccines' were widely sold commercially and even yet the ætiologic factor of common colds is unknown and the evidence of usefulness doubtful. The Council on Pharmacy and Chemistry is a safe guide to follow at a time when all sorts of untried therapeutic plausibilities are being launched on the medical profession.

Acne Rosacea

By SAMUEL AYRES, JR., M.D.

and

NELSON PAUL ANDERSON, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. C, 4th March, 1933, p. 645)

SINCE our recognition several years ago of the presence of *Demodex folliculorum* in the majority of our patients with acne rosacea and an allied condition which we have designated as pityriasis folliculorum (*Demodex*), our therapeutic results have been far superior to those obtained by the usual treatment of acne rosacea.

In view of the fact that Kaufmann-Wolf called attention to the frequent occurrence of *Demodex folliculorum* in the pustules of acne rosacea as long ago as 1925, it seems rather surprising that so little recognition has been accorded this valuable contribution. One might argue that, because *Demodex* is a more or less 'normal' inhabitant of the human skin, it is without ætiologic significance. Granting that the organism may be found on apparently normal skins, it usually is present in small numbers and may be found only by

expressing sebum from some of the oil glands by pressure. This is in striking contrast with the large numbers of *Demodex* that can easily be found in many cases of acne rosacea; it is not uncommon to find ten or fifteen organisms in a single tiny follicular scale or superficial pustule. It would be just as fallacious to say that, because the staphylococcus is found on many healthy skins, it is without any causal relation to furuncles or carbuncles.

In two previous communications we have called attention to the frequent occurrence of *Demodex* in acne rosacea and in pityriasis folliculorum (*Demodex*), a newly described clinical entity which is probably closely related to acne rosacea. On the other hand, we have been able to find *Demodex* only rarely in the pustules of acne vulgaris.

Our reasons for regarding *Demodex folliculorum* as an ætiologic factor of importance in these two disorders are as follows:

(1) The organism is easily found in from moderate to large numbers in pus from superficial lesions or in the dry follicular scales, whereas it is usually absent in acne vulgaris.

(2) A rapid clinical improvement or cure follows the application of strong anti-parasitic applications and the daily use of soap and water.

(3) Accompanying the clinical improvement there is a corresponding decrease in the number of *Demodex folliculorum* organisms that can be isolated from the skin.

Since the publication of these earlier reports, a total of seventy-seven patients in private practice have been seen who have presented the clinical picture of acne rosacea or pityriasis folliculorum (*Demodex*). The same conclusions that have been mentioned are applicable to this larger series. Of these patients, fifty presented typical cases of acne rosacea. During the same period of time that these cases were collected, only thirteen cases of acne rosacea were seen which failed to reveal *Demodex folliculorum*.

It was noted that a considerable proportion of the patients used soap and water infrequently or not at all. It is felt that the excessive use of cold cream and powder and the substitution of cleansing cream for soap and water favour the development and multiplication of these organisms. This may partially account for the recognized predominance of acne rosacea in women. A small droplet of pus obtained from a superficial pustule the size of a pinhead, placed on a glass slide and macerated with a drop of 40 per cent potassium hydroxide or glycerin, will usually show under the microscope from one to fifteen or more organisms. Usually the contents of two or three pustules are examined, or in those cases in which the complaint only of dry, rough skins is made, some of the minute dry follicular scales are picked off and examined in the same manner.

When such an examination shows the presence of *Demodex folliculorum*, local treatment alone will usually effect an improvement that is almost unparalleled in dermatologic therapy. Until recently we have employed an ointment such as is used for the treatment of scabies; betanaphthol, 2 gms.; sublimed sulphur, 4 gms.; balsam of Peru, 15 gms.; petrolatum, 15 gms. In spite of the fact that many of these patients have declared that their skin was so delicate that they could not even tolerate soap and water, we have obtained excellent results usually within from one to three weeks. The patient is instructed to wash thoroughly with soap and water every night and to apply the ointment for only three nights. There is usually a temporary increase of redness with some desquamation immediately following the application of the ointment, which, however, subsides in several days. It is usually necessary to have the patient repeat the ointment once or twice a week for several weeks. There have been but few recurrences in our series of cases, and those which have recurred have been rather mild and have responded promptly to further treatment.

More recently we have used Danish ointment in the same manner with equally good results and with less irritation.

We do not feel that the improvement is due to the effect of sulphur on the seborrhœa, because some of the most striking results occur in those cases presenting dry skins and with no evidence whatever of seborrhœa. The scaling mentioned in cases of pityriasis folliculorum is not of a seborrhœic type but rather consists of fine dry inconspicuous white scales about the mouth of the sebaceous ducts or the base of the lanugo hairs, resembling the frosting resulting from an ethyl chloride spraying. Microscopic examinations of the contents of pustules or scales made on each visit show a progressive diminution in the number of parasites until no more pustules or scales are available, which often occurs after the second or third week.

Of course, those patients who do not show *Demodex* must be treated according to the local and systemic indications in each case and undoubtedly a few of the cases with *Demodex* infection may need supplementary treatment, directed to the nervous system, gastrointestinal tract, and so on.

Summary and conclusions

(1) In seventy-seven cases of acne rosacea and pityriasis folliculorum (*Demodex*), *Demodex folliculorum* was found in superficial pustules and follicular scales in from moderate to large numbers.

(2) In sixty-nine of these patients whose results could be followed, striking clinical improvement or cure was obtained in all but three cases by the use of a strong antiparasitic ointment.

(3) Out of sixty-three cases of typical acne rosacea seen during the past two years, in which examination for *Demodex folliculorum* was made, the organism was found in fifty cases. With the exception of three patients who did not return for observation, excellent results were obtained in all but two of these cases by the use of a strong antiparasitic ointment without any other treatment.

(4) Irrespective of any argument concerning the causal relationship of *Demodex folliculorum* to acne rosacea, the fact remains that local antiparasitic treatment as described has given clinical results far surpassing anything in our experience with this disease.

Some Common Skin Affections of the Tropics and their Treatment

By W. E. COOKE, D.P.H.

and

HUGH WILLOUGHBY, D.T.M. & H.

(Abstracted from the *Journal of the Royal Naval Medical Service*, Vol. XIX, January 1933, p. 14)

THERE are many common skin conditions met with in those who serve or have served in the tropics which are easily recognized. We have selected some of the commoner skin diseases which pass through our skin department and quote the treatments which we have found successful.

Hyperidrosis.—General sweating, being usually dependent on some systemic disease, is of less concern dermatologically than localized sweating. The latter type has certain varieties, either neuritic in origin, where the skin area supplied by a particular nerve perspires freely, or due to hyperactivity of the sweat glands, especially in parts well heated by clothing or subject to 'folding', as in the case of the groins.

Anæmia, debility and alcohol are, of course, predisposing causes.

Treatment.—This depends entirely at what stage of the disease one is consulted in the matter. General health must first receive attention. Increase of tone in the muscles, as pointed out by Unna, should be a basis on which to begin: this can be accomplished by periodic stimulation, friction, etc.

The axillary and femoral areas are best tackled by means of (a) absolute cleanliness by frequent washing and (b) astringent applications followed by dusting powders. Formalin, one teaspoonful to a pint of water, is both cheap and efficient, and after dabbing on the affected area should be allowed to dry and not towelled. If the palms and soles are chiefly at fault it is important to recognize whether it is a 'hot sweat' or a 'cold sweat'. If hot, then wash the parts with weak borax solution, if cold bathe in hot water first, carefully dry the parts and apply

Rx		
Ichthyole	..	āā 5i
Olei terebinthe	..	5ss
Camphoræ	..	ad 5i
Unguentum zinci oxidi	..	

Local treatment must first be given by emollients and soothing ointments in cases where decomposition has given rise to dermatitis. Hebra's ointment (Emplastum plumbi cum vaseline) applied on lint is valuable.

Chromidrosis needs no special description and is often met with. Unfortunately, treatment is not very satisfactory, but scrupulous cleanliness and sponging, morning and night, with 1 : 1,000 perchloride spirit will do much to relieve the condition.

Urticaria.—The causation of this condition is threefold:—

(1) External irritants—stinging nettles, flea-bites and many other animal and vegetable substances used in washing, dyeing and cleaning clothes, etc., which may be classed as chemical irritants.

(2) Internal irritants—poisons conveyed to the skin by the blood-stream, such as drugs, e.g., copaiba, and foods, e.g., lobster, mushrooms, strawberries, etc.

(3) Reflex irritants—primarily intestinal helminthic infections or uterine and ovarian diseases. It is worth while bearing in mind that anomalous outbreaks of urticaria may often be an indication of liver diseases, such as cirrhosis and gallstones.

Two varieties of urticaria to which special names have been given are lichen urticatus (vel urticaria papulosa) and giant urticaria.

Treatment.—Obviously determination of the cause is the remedy—not always an easy matter. Allergic conditions must be sought for, and in this respect skin tests with various protein substances are useful.

Drug treatment for urticaria is limited, ichthyol given in capsules (adult dose min. v, t.i.d.) being the best. Salicylate of soda is always worth a trial, and purges will be found helpful in all cases.

Scabies.—This infection is too common to need description. Wrong treatment being, in our experience, more common than proper treatment, it is worth describing in some detail. There is a great temptation to overdo the sulphur baths, and the last state of the patient is often thus rendered worse than the first, caused by the infection itself. We recommend the following routine:—

(1) Bathe the patient in hot water containing sulphide of potassium 3 oz. to 30 gallons of water. Allow the patient to soak thoroughly for twenty to thirty minutes, then thoroughly scrub him with a strong nail-brush. (An attendant should do this to ensure thoroughness, and that all parts may be reached.) A further period of ten to fifteen minutes soaking should then be insisted on.

The patient is next rough-towelled and rubbed all over with sulphur ointment.

(2) While in the bath the patient's clothes should be steam disinfected, and besides clothing all bedding should be similarly treated.

The baths should be given once daily on three successive days, the inunction with sulphur ointment twice on the first day and once after bathing on the second and third days.

Disinfection of clothes and bedding should be done daily for three days.

Any further irritation after this treatment is due to sulphur ointment and not to scabies. Discontinuance of the ointment will cure this.

Furunculosis.—This is usually a staphylococcal infection of the hair follicles or sebaceous glands. Any condition causing debility and so lowering the resistance of the individual is a predisposing factor.

The urine of all patients suffering from furunculosis should be tested for sugar, as a transitory glycosuria occurs in severe cases.

Treatment.—Poulticing and early incision are inadvisable: indeed, incision in certain places such as the nose, upper lip and face generally may be followed by such serious consequences as thrombophlebitis, embolism, cavernous sinus thromboses, meningitis, septicæmia, pyæmia and even death.

Application of Unna's mercury and carbolic plaster gives excellent results. Cleaning with spirit or tincture of iodine and then painting with pure ichthyol and covering with a pledget of cotton-wool is excellent and should be renewed daily.

Application of a proprietary paste called 'Ilon' and deep subcutaneous and intramuscular injections of colossal manganese or manganese butyrate 0.5 to 1 c.c. every four or five days has been found to be very successful in bad cases.

Vaccine therapy (either stock or autogenous vaccines) is in our experience more useful in chronic cases than in the acute condition.

Tinea cruris.—Dhobie itch is so common that a description would be superfluous.

Treatment.—The first thing to be done is to cleanse the affected area thoroughly with soap and water. After so doing a variety of treatments may be tried, all of which are equally successful.

If severely inflamed, preliminary bathing with lotio calaminæ is advisable, or ichthyol, or a 10 per cent solution of sodium hyposulphite may be used.

Any of the following will then be found suitable applications:—

(1) Whitfield's ointment.

R̄ Acidi benzoici	.. }	āā gr. xv
Acidi salicylici	.. }	
Parafini mollis	..	5ii
Coconut oil	ad 5i

(2) Three per cent silver nitrate solution.

(3) R̄ Resorcinol	5i
Acidi salicylici	..	gr. v
Vaseline }	āā 5iv
Lanoline }	

(4) Liniment of iodine may be used on thick-skinned individuals, but is not advised for Europeans.

A dusting powder made of equal parts of boric acid, zinc oxide and starch should be used freely when necessary.

'Hong-Kong foot.'—This is a ringworm which is a very common occurrence abroad and persists in cooler climates unless energetically treated. The causal fungus is an *Epidermophyton*. Occurring as a rule during the summer months it starts as a vesicular eruption on or between the toes or in the hollow of the sole.

Treatment.—(1) Remove the epidermis by soaking well in hot salt water and then apply, night and morning:—

R̄ Acidi benzoici	.. }	āā gr. xv
Acidi salicylici	.. }	
Vaseline	ad 5i

(2) Obstinate cases react to

R̄ Chrysarobini	..	gr. xx
Acidi salicylici	..	gr. v
Vaseline	ad 5i

This ointment stains clothing, etc., and should be rubbed in after washing the feet in soapy water. The feet should afterwards be bandaged.

It is important to change the socks frequently and these should be disinfected before use.

A Simple, Precise Technique for Blood Transfusion

By HAROLD DODD

(Abstracted from the *Practitioner*, Vol. CXXX, No. 3, March 1933, p. 390)

Blood transfusion is probably not used so widely as it deserves. There are three possible reasons for this: (1) The technical procedure of grouping the bloods of the donor and recipient. (2) The impression that special training is necessary to use the fragile and expensive apparatus. (3) The old tradition still lingers, that it is a 'tricky business'.

Thanks to the initiative of the British Red Cross Society, many of our larger towns are provided with an established Transfusion Donor Service, the groups and Wassermann reactions of whose members are already determined. In exceptional urgency in a surgical case, the recipient's group need not be known, and a universal donor (group 4) can be used, after first testing the bloods together. In the absence of an available Donor Service, relatives or friends usually offer, but a donor tested against syphilis and malaria, if available, is preferable as there have been tragic cases of transmission of these diseases, for example, a son has given his father syphilis. Generally, the donor and recipient should be of the same group, and further their corpuscles and serum should always be tested together. The second objection, about the technique and apparatus, is not a real one; familiarity with intravenous therapy is essential, but this is now general as a result of the frequency of varicose vein injection; the apparatus is simple and can easily be improvised. A successful procedure depends on a punctilious attention to details, and this applies particularly to those who do emergency transfusions occasionally, when a simple, reliable method is essential.

The indications.—Between three hundred and five hundred women die annually from post-partum hæmorrhages, some of whom might be saved by a timely transfusion. This valuable help is available to the country practitioner, by ringing up his physician, surgeon or pathologist, all of whom do transfusions, and in a short time a donor or the collected blood is at the patient's bedside.

For instance, recently in the country, a transfusion was urgently needed after a severe post-partum hæmorrhage. The doctor sent a test tube of the patient's blood to a town with a likely donor (her husband). These bloods were matched, found to be compatible, and a pint was citrated and collected in a thermos flask. An hour later, the blood was injected.

This case illustrates the possibilities of the transportation of blood, by car, train or aeroplane. Transfusion is most useful in the emergencies of medicine, i.e., hæmatemesis (even while hæmorrhage is still going on); in surgery, before, during and after operation; and in obstetrical conditions. It is equally effective in adults and children. It renders partial gastrectomy, splenectomy and many other operations possible and safe; in the case of rectal carcinoma, transfusion has reduced the mortality from 20 to between 5 and 10 per cent.

The technique of the transfusion.—To collect blood, citrate it, and inject it, are the essentials of the procedure and surely simple; but every conceivable accident has occurred to make it seem difficult and fraught with pitfalls.

The apparatus.—I have tried several methods and specialized apparatus and experienced numerous mishaps. The following simple, old technique is available or can be improvised from material in doctors' surgeries, chemists' shops and hospitals. It consists of:—(a) Sterile dressings for the patient and donor. (b) A Record syringe 5 or 10 c.cm. for several purposes, but chiefly to act as a handle to insert the needle into the veins. (c) Three new or sharpened Record needles: (1) a fine hypodermic, to inject the local anæsthetic; (2) a large bore needle to withdraw the donor's blood;

when this acts as a control—is administered blood is are pre-blood-p use as prepara flask to boiling, 1 in 46 thermc to the solutio on its thoul blood, lost. here meas and t able pint do as or th piece rubb the Rec intr vein artery forceps.

28-3-36.

In a fat or bloodless recipient, the following instruments will expose the vein by cutting: (1) A scalpel or sharp pocket knife, dissecting forceps, aneurysm needle, and a pair of pointed scissors. (2) Ligatures: catgut or thread to tie the vein and suture the skin. (3) A cannula, or the Record serum needle, will be equally efficient and avoid dividing the vein.

The operation.—This resolves itself into three stages: (1) Testing the bloods. (2) Collecting and citrating the blood. (3) Injecting the citrated blood.

Testing the bloods.—This is admirably described in Denis Browne's article, as follows:—

'Pipettes, test tubes, wooden sticks for stirring the blood, Hagedorn needles for pricking the skin, a white glazed tile on which to examine the bloods, a grease pencil for writing on it, a lens to magnify the reaction, a bottle of normal saline and a bottle of spirit. The Moss grouping is a very useful indicator of what the reactions of blood are likely to be, but before transfusion it should be determined what the reaction actually is. For this, about 2 c.cm. of each blood is needed, and in many cases that of the recipient can be obtained from an operation wound, an injury or the placenta. Two drops are picked up with a pipette and blown into 5 c.cm. of saline. The rest is allowed to clot or is centrifuged in order to separate the serum. A drop of each serum is mixed with each opposite solution of corpuscles in a patch of the tile that has been isolated and labelled by the grease pencil. The mixture is then watched for any clumping of the red cells. The dilution of the donor's blood makes the reaction easy to interpret by preventing rouleau formation, and if agglutination occurs (this means incompatibility), it results in a very characteristic "cayenne pepper" appearance of red granules in the clear serum. If possible, twenty minutes should be allowed to elapse before it is decided that the bloods are compatible, but it is usually possible to make out the result in the first five minutes after they are mixed'.

The collection of the blood.—Examine both arms of the donor and select a large vein, the median basilic being the most suitable. In London many donors have several puncture scars, some as many as twenty. It is unnecessary to 'cut down' on a donor's vein to collect blood; donors object to it strongly, and the Transfusion Service forbids it in their members. If the veins are

(they are occasionally in obese or women arm in a dependent position for five water; in addition, put the blood-bag round the arm and pump it up when there is usually no difficulty in the vein. Loosen the donor's neck and he lies on a firm, high table; I prefer the. Before use, rinse everything with solution.

the donor's arm, from the shoulder to the limb can then be handled by the hands, pulse felt, etc.). Inject a c.cm. novocain intradermically over the site. This anæsthetic is not a courtesy to the donor. The large needle can thus be used. Massaging this spot with a sterile cloth to remove any small resulting swelling which might

the anæsthetic is taking effect, fit the large syringe and, with citrate solution, fill it several times, and finally half-fill it. Use the Record needles, take care to cover them with a protector, lint, etc., when they are dropped into the tray dish, the point may be knocked off, it back, thus jeopardizing, before the successful entry into the vein. Repeatedly care due to this unnoticed incident.

the rubber tubing or blood-pressure bag over the selected vein; if tubing is used, tension so as not to affect the strength of the veins are distended by the arterial flow. The blood-pressure apparatus is more accurate and comfortable for the donor and patient alike; I apply it at a pressure of 50 mm. (venous pressure being about 30 mm.).

(4) With the donor's arm out at 45° on an arm rest, the vein is punctured by transfixing both its walls with the needle, the opening facing upwards, then rotate the needle 180° (this is important), thus the opening faces downwards; now, whilst sucking with the syringe, the needle is very slowly withdrawn, until blood appears copiously in the barrel. This method ensures entering the vein; the essential is to introduce the needle firmly enough to pierce cleanly, and not to push the wall of the vein before the point. An alternative method of entering the vein is to puncture it with the needle opening downwards, as in the second stage of the former method. This is advocated by some as being less likely to fail to draw the blood. The ultimate result is the same; it is a matter of personal preference.

When the donor's skin is thick or scarred by previous punctures, entering the vein may be facilitated by making a tiny nick $\frac{1}{2}$ in. long in the skin with a pointed scalpel; thus the needle point can be placed actually on the vein before attempting to enter it. When blood enters the syringe, the assistant places the glass jar (containing the stirrer and 2 oz. of 4 per cent citrate solution) beneath the needle; the syringe is gently detached, and the blood flows briskly into the jar; the arm may need turning slightly. The surgeon steadies the needle throughout the collection period, usually five to ten minutes. The blood is slowly stirred by the assistant or the operator, the jar standing on an adjusted stool. The conventional rubber tubing on the needle to lead the blood into the jar is unnecessary; it adds to the risk of clotting by increasing the foreign surface over which the blood must pass.

(5) The donor is watched and given a warm drink should he feel faint; it is advisable to offer this before the transfusion begins. He takes a bandage in the hand of the arm being used, and squeezes it slowly and firmly 10 to 20 times per minute; this helps the expulsion of the blood—a quick collection minimizes clotting in the needle and cooling. When the amount required is secured, the band round the arm is gently released, the vein is collapsed by a swab placed firmly over it where the needle enters, and the donor's extended arm is carried upwards, when the needle is

withdrawn. A firm dressing is pressed over the puncture, and the elbow (still raised) is firmly bandaged (bandage in donor's hand). Acutely flexing the elbow after removal of the needle and while bandaging encourages hæmatoma formation by obstructing the venous return.

This is elaborate treatment of a needle puncture, but stiffness of the elbow, cellulitis, phlebitis, hæmatomas, small abscesses and axillary adenitis have occurred, causing pain, temporary disability and inconvenience; if care is taken, they never occur. The donor is then given a meal, thus ensuring rest and nourishment after the loss of blood. Donors are instructed to remove the wool of the dressing next day.

Difficulties may arise during the collection. Failure to enter one vein calls for trial of another. The blood may clot in the needle; try passing a stilette, but this is not usually effective, so take the needle out and a brisk stream of blood often follows. By turning the sterilized arm towards the flask this is caught. This vigorous flow often completes the desired quantity; that it has touched the sterilized skin is no bar to its use. The blood is carried to a safe place (accidents have happened through omitting this precaution); to keep it warm it is stood in an enamel jug containing water at 110°F., covered by sterile gauze. A jug is better than a bowl; the jar may topple over in the latter. If a thermos flask is used, the boiled cork is inserted, and the blood is ready for transport.

The injection of the citrated blood.—The patient lies undisturbed in bed. If an assistant is available, whilst the blood is being collected, an intravenous saline to the recipient can be slowly given, thus the blood can be introduced without delay. In an urgent case this intravenous saline can be started before drawing the blood; it may keep the patient alive during a critical 15 minutes, for example in a ruptured spleen or kidney.

The injection should take from 40 to 60 minutes; this slow introduction is vital to the complete success of the transfusion. Any less time risks: (a) collapse, due to heart failure, precipitated by the rapid increase of circulating fluid. This is not unlikely in aged toxic or debilitated patients. As a prophylactic, before the transfusion, give an injection of digitalis gr. 1/100 or diginutin $\frac{1}{2}$ dr. (B. W. & Co.) by mouth. (b) A brisk reaction due to some incompatibility of the bloods and not allowing time for dilution of the 'foreign' serum and corpuscles; this causes tingling pain throughout the body, backache, restlessness, air-hunger, faintness, thirst, sweating, rigors, and occasionally sudden vomiting or call to defæcate; the pulse quickens and the temperature rises. To avoid this, take 10 minutes to inject the first 2 ounces, and carefully observe the patient.

The patient's eyes are lightly covered, and he is moved to the side of the bed where the surgeon proposes to work. A good light is essential. Even in collapsed patients, it is often unnecessary to 'cut down' on the vein. If the limb is hung down and the blood-pressure bag applied to the arm at 50 mm. Hg, the median basilic and median cephalic veins will fill sufficiently for puncture by a sharp, fine serum needle. Prepare the arm and place around it the rubber tubing or blood-pressure bag, tensioned as already mentioned. Take the funnel and tubing, and rinse with normal saline, carefully expelling the air bubbles until the fluid flows through freely, leaving the funnel half full. This ensures that the tubing is patent; occasionally I have found it choked by clots from a previous transfusion. The assistant holds the apparatus, or, if working single-handed, it is suspended from a stand, hook, or bed-rail above the patient's arm. The rubber tubing is occluded by the assistant's fingers, or an artery forcep.

Insertion of the needle into the recipient's vein.—Half-fill the Record syringe with citrate solution, fit the serum needle to it, carefully inspecting its point. Deliberately transfix the vein, rotate the needle, and withdrawing suck with the syringe; blood usually enters, and, if so, proceed carefully as follows: (1) Unclick the

rubber tube round the patient's arm (this permits venous return again). (2) Inject the blood and citrate in the syringe into the vein. By this step the needle is cleared of blood and filled with citrate solution; thus the recipient's blood cannot clot in the needle (I have seen this happen) during the brief interval between the detachment of the syringe from and the attachment of funnel and tubing to the needle. Occasionally, by omitting to unclip the band round the arm, many minutes have been lost determining why, although the needle was in the vein and blood oozed briskly from it, yet the citrated blood would not run in. When connecting the needle to the tubing, take care not to jerk the needle out of the vein, and, when accomplished, secure them by a ligature, as they occasionally slip apart. A Record syringe adaptor makes this much easier.

Failure to enter the vein by needle calls for exposure by cutting. Anæsthetize and incise the skin over the median basilic vein, which is defined for $\frac{1}{2}$ in. and tied at its lower end. Place another ligature with the first knot loosely tied round the upper end of the vein (this is in readiness to retain the cannula).

Take the dissecting forceps in the left hand, pinch up about half the circumference of the vein about the middle, then with the scissors transversely snick this elevated part below the forceps, lift slightly; this further increases the opening so that the cannula (securely attached to the funnel and tubing containing saline) can be slipped well into the vein and retained by tightening the hitch of the already placed ligature. Allow the saline to flow and slowly introduce the blood, the first 2 ounces in 10 minutes, and thereafter 1 ounce every two minutes. Small soft clots sometimes form in the blood, and are separated by filtering it through a small piece of gauze over the funnel mouth. The reservoir or funnel is kept warm by hot towels; being small, the blood runs through quickly, and as the main bulk in the jar is in water at 110°F., cooling is slight.

During the injection, carefully observe the patient's pulse and appearance. Any untoward occurrence should be treated promptly. If necessary, stop; the blood can be kept warm and used later. On the other hand, a pulseless, blanched and unconscious patient may regain consciousness towards the end of it. One patient, a doctor with jaundice due to stones in the common duct, after a transfusion for secondary hæmorrhage, stated that he felt he was definitely recovering after a transfusion, whilst before it, he felt so ill he feared he was going to die. Many patients positively date their improvement from the time of a blood transfusion, whether the illness is due to hæmorrhage or severe sepsis; it certainly is a powerful aid to recovery. The apparatus is flushed immediately after use, ready for the next occasion; this avoids clotting in the tube, which might hinder or ruin the next transfusion.

Observe all the joints of the tubing and glass throughout; they sometimes slip or leak, and valuable blood has been lost in the resulting mess! Fixing the tubing and cannula (or needle) to the arm for several inches with strapping in the line of the vein will prevent the movements of a restless patient jerking the cannula from the vein. Occasionally the blood stops flowing; this may be due to an air bubble or clot in the tube or needle, or to the cannula orifice being in contact with the vein wall. The stream can be restarted by 'milking' the tube between the fingers and thumb, or by straightening the cannula in the vein; if this fails, wash the apparatus through with saline and begin again.

Transfusion, like other urgent remedies, should not be withheld too long, although it is never too late to try; a precautionary transfusion always gives beneficial results, but, if too long delayed, life-saving opportunities may be lost.

Use of Histamine in the Treatment of Pruritus

By A. CARLTON ERNSTENE, M.D.

and

BENJAMIN M. BANKS, M.D.

(Abstracted from the *Journ. Amer. Med. Assoc.*, Vol. C, 4th February, 1933, p. 325)

MILLET AND BROWN have treated patients with angioneurotic edema by repeated injections of small amounts of histamine and have obtained favourable results in a few instances. Several months ago, we administered the drug to a patient with severe generalized urticaria and constant, intense pruritus, three weeks in duration. Epinephrine, ephedrine, and calcium salts had failed to give relief. The first subcutaneous injection of 0.5 mg. of histamine resulted in complete disappearance of pruritus within twenty minutes. The wheals, however, were not appreciably affected. Eighteen hours later the pruritus returned. A second injection of the drug given at that time resulted in complete relief from itching within ten minutes and disappearance of all wheals within half an hour. Histamine was then administered twice daily for five days. Although wheals returned from time to time, their number constantly diminished, and they were not accompanied by pruritus except on two or three occasions. Each injection of histamine resulted in prompt relief from itching, when present, and gradual disappearance of the wheals. At the end of five days the patient was free of all symptoms and had only an occasional wheal. Three months later there had been no return of urticaria.

Because of this striking therapeutic result and the apparent effectiveness of histamine in relieving pruritus independently of its effect on urticarial lesions, the drug was administered not only to a small series of subjects with pruritus accompanying urticaria but also to a number of patients with itching due to other conditions. In all but one subject the customary therapeutic measures had been employed previously and without relief. The drug usually was administered in amounts of 0.5 mg. twice daily, but in one subject 1.0 mg. was given three times a day for several days and in two with bronchial asthma the first one or two injections were reduced to 0.2 or 0.3 mg. Doses of 0.5 mg. usually caused moderate to intense flushing of the face and neck with transient headache, and occasionally the subjects noticed palpitation for a few minutes. No untoward reactions were encountered, but the drug was not administered to patients with myocardial insufficiency or angina pectoris. Doses of 0.5 mg. did not precipitate asthmatic attacks in the two subjects with bronchial asthma. All patients were kept in bed for one hour after each injection of histamine.

RESULTS

Thirteen patients in all were treated, and over half of these obtained at least temporary and partial relief from itching. Five patients in addition to the case just reported had pruritus associated with urticaria. One was completely relieved for two hours after the first injection of the drug, while another reported partial relief after the second dose of histamine and was practically free of symptoms after the third injection of the drug. In both of these patients, urticaria and pruritus subsequently returned. Further treatment with histamine gave partial relief in the first but was ineffective in the second. In one other subject with urticaria, the symptoms almost completely disappeared during the period of treatment, but improvement occurred so slowly that the possibility of spontaneous convalescence must be considered.

Seven of the thirteen subjects treated with histamine had pruritus due to conditions other than urticaria, and four of these were benefited by the treatment. One patient with pruritus vulvæ, three years in duration, obtained lasting and practically complete relief from

itching. Another, who had had severe pruritus of undetermined etiology in the crural regions for one year, was almost entirely free of symptoms for three weeks after four days of treatment. Partial relief from itching was obtained in one subject with severe, generalized dermatitis of unknown cause, eighteen months in duration, and in another with pruritus due to kraurosis vulvæ, seventeen years in duration. The three patients in this group who failed to obtain relief from histamine all had pruritus ani.

Favourable results from the oral administration of ergotamine tartrate in the treatment of urticaria have been reported and the drug has been employed successfully by mouth as an anti-pruritic agent. Several of our patients were given ergotamine tartrate (Gynergen) by mouth in doses of 1 mg. three times daily for five days either before or after treatment with histamine. In none was a favourable therapeutic response observed.

With the exception of one subject with urticaria, all the patients who were benefited by treatment with histamine showed distinct improvement or were almost completely relieved of pruritus after the first one to three injections of the drug.

No explanation is available for the favourable therapeutic responses obtained nor is it known why histamine should be effective on one occasion and subsequently fail to relieve a relapse of symptoms. Millet and Brown have suggested that repeated injections of small amounts of histamine produce a state of tolerance to the drug and that this is accompanied by a diminished reactivity of the skin. This, they believe, explains the therapeutic effect of the drug in certain patients with angioneurotic edema. They, however, employed much smaller doses of histamine than were used in the present investigation. No evidence of diminished sensitivity to histamine was observed in our patients, and the prompt relief of symptoms in the favourable cases seems to indicate that the results were due to some other mechanism than a change in tolerance to the drug. The direct effect of the drug on the minute vessels of the skin may be the responsible factor.

The results obtained in the present study warrant further investigation of the value of histamine in the treatment of pruritus. This report is submitted in the hope that other investigators may have an opportunity to employ the drug, so that its therapeutic effectiveness may be evaluated by observations in a large number of patients. It would be of interest to observe the effect of the drug on the pruritus of such dermatologic conditions as lichen planus and pityriasis rosea and on itching associated with jaundice, uremia, lymphoblastoma and leukemia.

SUMMARY AND CONCLUSIONS

(1) Histamine was administered subcutaneously, usually in doses of 0.5 mg. twice daily, to six patients with pruritus associated with urticaria and to seven subjects with pruritus due to other conditions.

(2) Three of the six patients with pruritus accompanying urticaria were promptly benefited by the treatment. In one of these, lasting and complete relief from itching was obtained. In the other two, complete or practically complete relief was followed by a relapse of pruritus. Subsequent treatment with histamine failed to cause improvement in one of these and was only partially effective in the other.

(3) Four of the seven patients with pruritus due to conditions other than urticaria were improved by treatment with histamine. One patient with pruritus vulvæ, three years in duration, obtained lasting and practically complete relief from itching. One patient with pruritus of undetermined etiology in the crural regions, one year in duration, was almost completely relieved of his symptoms for more than three weeks. Partial relief of itching was obtained in one patient with generalized dermatitis of unknown cause and in another with kraurosis vulvæ. The three patients in this group who received no benefit from the treatment with histamine all had pruritus ani.

(4) Five patients were given ergotamine tartrate by mouth in doses of 1 mg., three times daily for five days, either before or after treatment with histamine. In all, ergotamine failed to relieve the itching.

(5) The results of the present study warrant further investigation of the value of histamine in the treatment of pruritus.

The Treatment of Auricular Fibrillation and Flutter

By THOMAS F. COTTON, M.D., C.M., F.R.C.P.

(From the *Practitioner*, June 1933, Vol. CXXX, No. 6, p. 698)

THE discovery of the action of digitalis in heart disease by Withering more than 150 years ago was a clinical observation which must be reckoned a landmark in the field of medical science and practice. The chance information which he had obtained from a family recipe proved a turning point in the history of the treatment of heart failure. The experience of this acute clinician established on a secure foundation a drug which is now recognized as satisfying the exacting standards required of a specific remedy. He reveals the spirit of scientific rectitude which guided him in his investigations, when he writes in a letter to a friend concerning the use of digitalis: 'It is much easier to write upon a disease than upon a remedy. The former is in the hands of nature, and a faithful observer with an eye of tolerable judgment cannot fail to delineate a likeness. The latter will ever be subject to the whims, the inaccuracies, and blunders of mankind.' After ten years' experience he published his results in a memorable treatise which will always remain a milestone in the story of digitalis therapy. Although impressed by the effect of digitalis as a diuretic he realized that it had a definite action on the heart. His recommendation to give it in sufficiently large doses until it acts on the kidneys, the stomach, the pulse, or the bowels, is advice which could not be improved upon at the present time. For more than a century no progress was made in the treatment of heart disease with digitalis. The great advance in our knowledge of its use came when Mackenzie by clinical bedside observations discovered the specific action of the drug in what we now know to be auricular fibrillation. Clinical experience in the treatment of auricular fibrillation in its relation to heart failure has proved the value of his work.

The most critical moment in the history of a cardiac malady is the onset of congestive failure; the symptoms are characteristic, the clinical effect profound, and the causal mechanism is in the majority of cases closely related to a disorder of function produced by fibrillation of the auricles. With the onset of auricular fibrillation the auricles are virtually paralysed, rapid and irregular impulses are transmitted to the ventricles, and the contractions of these chambers are rapid and grossly irregular. This disordered action of the ventricle places a heavy burden on the heart muscle, and when there is underlying myocardial disease symptoms and signs of muscle weakness develop rapidly and cardiac failure is imminent in untreated cases. This disordered rhythm may occur in paroxysms lasting a few minutes, several hours, or occasionally days before the normal rhythm is restored. In the intervals between the attacks there may be no symptoms referable to the heart, and if the myocardial defect is slight the attacks do not lead to serious consequences. Infrequent and short paroxysms are not disabling and therefore do not require special treatment. They are sometimes related to an infective process, and when this has been controlled the attacks may not recur. Paroxysms of auricular fibrillation are a common complaint in young subjects with rheumatic heart disease, particularly in those with mitral stenosis; in older patients with degenerative changes in the myocardium and arteries; and in a well-defined group with thyrotoxicosis.

The main object of treatment in the attack is to make the patient comfortable until the normal rhythm is restored; reassurance as to the nature of the seizure is often required, and a sedative will help to remove a natural anxiety. A chloral hydrate mixture in 10 grain doses, repeated at four or six hourly intervals three or four times, is useful for this purpose. Chloralamide in cachets, gr. 10, repeated in the same way is equally effective in calming the patient. An ice-bag applied to the precordium may relieve the discomfort felt in the region of the heart. Firm pressure on the carotid sinus over the carotid artery below the angle of the jaw for ten or fifteen seconds may release a mechanism, through the vagus nerve, which can terminate the attack. If vomiting is induced the paroxysm may be shortened. Quinidine sulphate gr. 3, given every four hours, is the only drug known to have a specific effect in controlling this disturbance of rhythm. Digitalis should be withheld as it may establish a chronic state of fibrillation. A prolonged rest is not required after the normal rhythm has returned unless symptoms of heart failure have developed during the attack. Quinidine may be prescribed between the attacks for its effect in lengthening the intervals and shortening the duration; the dose is gr. 3 t.d.s.; if necessary it can be increased to gr. 15 in the twenty-four hours; a good practice is to prescribe the extra gr. 6 to be taken at bedtime; the patient need not be kept at rest on this dosage.

When auricular fibrillation has lasted for a longer period than ten days it will not revert to a normal rhythm spontaneously, and is a chronic malady. This rapid and irregular action of the heart when established is the chief cause of congestive failure and is always a serious condition in untreated cases. Symptoms of heart failure develop rapidly in those with advanced structural disease, such as mitral stenosis with much enlargement, hypertensive heart disease, and coronary atheroma. In others without chronic disease of the heart muscle symptoms of myocardial exhaustion may be delayed and the circulation well maintained for a long period.

The object of treatment is to relieve the heart of the heavy task which the rapid ventricular rate produced by the fibrillation has imposed on the ventricles. The slowing of the increased ventricular rate can be obtained by giving digitalis in doses which are large enough for the drug to accumulate in the tissues of the body. The usual practice is to give a drachm of the tincture daily for five days or a week, when the ventricular rate may be expected to fall to 70 or 80; at this level the dose should be halved, and continued so long as the rate does not fall below 60. Profound slowing, with coupling, nausea, vomiting and diarrhoea, as evidence of over-dosage, are indications for withdrawal of the drug and complete rest. When these toxic effects have disappeared, digitalis control can be resumed in the amount required, and given as a maintaining dose if the heart rate reaches 90 per minute at rest. Gastric symptoms may be avoided by prescribing the drug well diluted and after food. The patient should always be kept at rest when digitalis is given in large doses during the initial stages of the treatment. It is sometimes necessary to obtain a quick response and a rapid slowing of the heart by giving the drug in massive doses. The dosage in these circumstances for an adult with body-weight of 140 lbs. is 1½ to 2 drachms of the tincture in a single dose, and repeated twenty-four hours later if the rate remains high, followed by 20 to 30 minims daily. Massive dosing is dangerous if there is digitalis in the body at the time, and the patient cannot be kept under close observation, for the toxic effect may be rapid and produce fibrillation of the ventricles and sudden death. The daily administration of 20 minims of the tincture is a minimal maintenance dose for an adult; a smaller dose is not sufficient to control the rate, for a larger amount, averaging 20 minims, is destroyed daily by the body tissues. The white Nativelle's granule digitalin, gr. 1/240, is the equivalent of about 20 minims of the tincture, and is a convenient

and reliable preparation. The tincture of strophanthus is sometimes prescribed when digitalis is not tolerated. The initial doses are 20-30 minims daily. Compared with digitalis it is an unsatisfactory drug and is rarely required as a substitute. Strophanthin can be given in case of urgency. An intravenous injection of gr. 1/250 in 1 drachm of saline and repeated in two hours produces a rapid slowing of the ventricles; it should precede and never follow digitalis administration. The dosage of digitalis or strophanthus can be determined with a considerable degree of accuracy by giving the patient the quantity that makes him most comfortable. The ventricular rate should not be lowered below 90 when there is fever, as the cumulative effects of overdosage can occur if lower rates are maintained.

Our main objective in treating auricular fibrillation is the control of the heart rate. It is possible to obtain this object in some patients by restoring the normal rhythm with quinidine. The results are dramatic, and there is very little risk in selected cases. The most suitable for quinidine therapy are those presenting few signs of structural disease, with no enlargement of the heart and no valve disease. This drug should not be given if there is much enlargement, congestive failure, or a history of hæmoptysis. Quinidine may have to be prescribed in large doses up to 30 grains daily and continued for a week or longer before the fibrillation is replaced by a normal rhythm. Absolute rest in bed is essential, until the fibrillation is abolished or the treatment discontinued; it is desirable to keep the patient in bed for a fortnight after the normal rhythm has been restored. If the fibrillation persists after ten days of treatment the daily administration of quinine, gr. 30, may be continued for a further period of a week or ten days, but is not likely to be effective in restoring the normal rhythms. The initial dose should be small, in case there should be any idiosyncrasy for this drug; gr. 3 the first day, gr. 6 on the second day, and on the third day gr. 6 three times daily, and afterwards gr. 30 evenly spaced over the twenty-four hours. When the rhythm has returned to normal the dose should be reduced to gr. 6 two or three times daily for a week, and afterwards gr. 12 daily for a month or longer.

Auricular flutter is a disorder of the heart's rhythm caused by the rapid and regular beating of the auricles with the rate between 260 and 320 to the minute. The ventricular rate is increased and is usually half the auricular rate, i.e., 130 to 160 per minute. Conspicuous rapid and regular heart action which is persistent and is unaffected by change of posture or exercise is a characteristic feature of this condition. When the ventricles beat rapidly and irregularly, as they may do, it is difficult to distinguish auricular flutter from auricular fibrillation without the aid of an electro-cardiogram. The two conditions closely resemble one another in their causal mechanism. In both there is a disorder of rhythm caused by a circulatory wave in the auricles; in fibrillation the wave travels at a more rapid rate, and takes a more irregular course. This circus movement in the auricles is responsible for the rapid contraction of the ventricles, and the clinical effect resulting from the increased ventricular rate. In patients with auricular flutter, as in those with auricular fibrillation, a heavy load is thrown on the ventricles, and the object of treatment is to relieve the heart of this extra work by slowing the ventricular rate. This can be done by giving digitalis in sufficiently large doses to produce the required slowing of the ventricles, and by continuing the use of this drug in doses that will maintain a slow ventricular rate. This remedy has a specific action in flutter as in fibrillation, and in the general management of the cases the rules governing its administration are the same. The initial doses are heavy, a drachm a day of the tincture for a week, followed by a daily maintenance dose of 20-30 minims. When the rate of the ventricles has reached 70 or 60, the heart may become grossly irregular with the onset of auricular fibrillation, and if the drug is discontinued at this stage the fibrillation

may be of short duration and the normal rhythm permanently restored. In the majority of treated cases chronic fibrillation is established and the ventricular rate can be controlled by resuming treatment with digitalis. In some, if the patient is kept digitalized, the flutter persists, a high grade of auriculo-ventricular block is produced, and the ventricles beat at a slow rate, and heart failure can be arrested.

Quinidine can be employed with the object of restoring the normal rhythm, and is sometimes successful, but in most cases is an unsatisfactory remedy. The dosage and the management of the case is that of auricular fibrillation.

Paroxysmal flutter is rare as compared with paroxysmal fibrillation, but the treatment is the same and need not be described.

Auricular fibrillation is a disorder of rhythm frequently observed in thyrotoxic subjects. The treatment is that of toxic goitre. A normal rhythm returns after a thyroidectomy in about half of the cases so treated. If after the operation fibrillation persists a normal rhythm can be restored with quinidine. Treatment with quinidine before the operation is rarely successful. Digitalis should be given before operation if the ventricular rate is high and congestive failure imminent. It is only in exceptional circumstances and when the patient is moribund that auricular fibrillation contra-indicates thyroidectomy.

The Toxæmias of Pregnancy

By WM. J. STEVENS, M.D., C.M., F.R.C.S.

(From *The Canadian Medical Association Journal*,

May 1933, Vol. XXVIII, No. 5, p. 513)

The toxæmias of pregnancy may be classified into the following groups:

- (1) Pernicious vomiting of pregnancy.
- (2) Nephritis complicating pregnancy.
- (3) Low-reserve kidney.
- (4) Pre-eclamptic toxæmia.
- (5) Eclampsia.

It is generally recognized that the toxæmias of pregnancy (apart from those of purely nephritic origin) are closely related to one another and that the underlying cause is a complicated disturbance of metabolism.

PERNICIOUS VOMITING

The simpler nausea of pregnancy without vomiting may be due to various factors—neuroses, displaced uteri, cervical erosions, adhesions, or constipation. It is frequently checked by suggestive measures, and the success of such measures would seem to prove that the condition is not essentially a pathological one.

One of the functions of the placenta is to store glycogen for the growing fetus until the foetal liver is able to store its own reserve carbohydrate, and, during this period, it is the glycogen of the maternal liver upon which it draws for its supply. At the end of the third month, the time vomiting ordinarily ceases, the foetal liver is formed and able to store its own glycogen, and then, in ordinary circumstances, the drain on the maternal liver should cease. The continued and increased demand for glycogen on the part of the rapidly growing fetus drains the glycogen content of the maternal liver. True hyperemesis is a condition of uncontrollable and pernicious vomiting sustained by a vicious circle—vomiting, starvation, acidosis. The acidosis which is so prominent a factor in the last stage of pernicious vomiting is not only a result of the intolerance of the stomach for food, but tends to increase that intolerance and so to prolong the nausea and vomiting. The gastric elimination may give rise to an alkalosis, a corollary of the cerebral oedema, the cause of headache, dullness, stupor and convulsions in fulminating cases of hyperemesis, or acute yellow atrophy, showing the ætiological relationship between the toxæmias.

In early pregnancy the carbohydrate deficiency results from a combination of a low carbohydrate-intake on the part of the mother, plus the extra burden of foetal requirements. Almost invariably, mothers report a preference for protein foods and an indifference to or even dislike for carbohydrates, especially sweets. Sometimes they diet to reduce their weight. If a diet rich in carbohydrate is supplied the foetal glycogen demand from the maternal liver, as the glycogen store-house of the body, can be met. Glucose will apparently check nearly all the toxæmias of pregnancy in their early stages and will benefit remarkably many in the later stages. Glucose infusion not only corrects the existing carbohydrate deficiency but restores and stimulates the liver cells which have been destroyed by the toxæmia.

Indifference to the vomiting of pregnancy, looking upon it as a natural physiological consequence of the pregnant state, has led to many catastrophes. Too many women are themselves prone to accept it as the inevitable consequence, and often, before it is realized, a grave pathological state has developed from what was originally considered only a minor discomfort. Preventing the simple from becoming the complex by careful antenatal watching, and treating the condition in its incipency, should therefore be the criterion of any system of treatment which is advocated. It is possible, in all circumstances, at least to make the patient more comfortable.

Treatment.—Isolation, early, in a hospital is, of course, most desirable, but if kept at home the patient should be in the brightest and sunniest room, as far away from the kitchen as possible. She should be relieved of cooking and should rest in bed in the morning. She should sleep alone. The anxious husband, family, and visitors must be excluded. Complete confidence in the doctor and nurses must be obtained, and co-operation and the exercise of the patient's will-power assured by the strongest encouragement. A complete physical examination is made and appropriate treatment instituted for any abnormal pelvic condition. The CO₂ (which is generally low, and the blood predominate) are estimated.

No food should be administered by mouth for forty-eight hours, so as to rest the stomach. Glucose, preferably 250 c.c. of a 25 per cent glucose-saline solution per hour, should be given intravenously at body temperature, morning and night, beginning immediately on admission. The stronger the solution of glucose, the more rapid and lasting are the effects; the more strongly hypertonic favours a more rapid interchange between the tissues and the blood. Normal saline, 500 c.c., may be given daily by hypodermoclysis, or intravenously if marked dehydration is present. A cleansing enema is given every morning. Rectal instillations of glucose (drams 4), sodium bromide (grs. 60), and saline to make 6 ounces, are given slowly every four hours. Small blood transfusions of 300 c.c. of human blood by the direct method, to which may be added 500 c.c. of normal saline, have given satisfactory results, when glucose fails to produce improvement. Luminal, grs. 1½, is given by mouth or hypodermically, to assure sleep at night, or to allay nervousness during the day. The fluid intake and output are measured daily. A duodenal nasal tube (which may be kept in place for days), with the injection of 10 per cent Karo syrup and skimmed lactic acid milk or butter-milk; or 5 per cent Dryco, with or without luminal, can be used, beginning with 50 c.c. per hour up to 300 c.c. per hour, according to the patient's tolerance (glycosuria or diarrhoea).

With the patient's assurance of retaining certain articles of diet after a usual favourable response within two or three days, when the vomiting lessens and the patient begins to feel hungry, a dry diet is gradually begun, consisting of buttered toast, rice, potato, jam, marmalade, baked apple, fruit juices, advancing to chicken or fish and some vegetables or broth. Ginger ale or butter-milk is sometimes retained. At this stage,

glucose may be discontinued intravenously and continued by mouth and rectum. A laxative may supplant the enema. The patient is advised to refrain from fatty foods (which are incompletely oxidized) and is encouraged to drink at least 1½ quarts of fluid daily. Milder cases are treated with a high carbohydrate diet of solid food, in small meals at frequent intervals, with resting between feedings. A glucose mixture consisting of 1 lb. of glucose plus 1 quart of water, with the juice and chopped-up skins of two lemons added, boiled 5 minutes, strained, and taken during the twenty-four hours, contains 1,000 calories and is beneficial.

The injection of 10 c.c. or more of the husband's blood intramuscularly into the patient's buttocks, twice weekly or oftener, sometimes helps to alleviate the vomiting. The theory is that the blood of the foetus may be of different type from that of the mother but the same as the father, so that the husband's blood renders the mother, by desensitization, immune to the foreign protein. Gastric lavage may be resorted to after each vomiting, if the patient vomits persistently. A good response is often found. Removal of the vomiting pain sometimes aids, so that if the patient vomits she must do so on the floor or on the edge of the bed.

Ovarian extract (whole ovary), or corpus luteum, in conjunction with the other routine, is used, in doses varying from a gr. 5 tablet every three hours to an intravenous injection of 1 c.c. or more every two hours, on the assumption that the ovary sometimes fails to produce a hormone stimulating the excretion of pituitrin into the cerebrospinal fluid, which, entering the circulation, helps to empty the uterus and to start the flow of milk; as a result of this hormonal deficiency, toxæmia follows, which may be neutralized by saturation of the patient with ovarian extract.

However, all cases of pernicious vomiting cannot be relieved by injections of glucose; sometimes all measures fail. In such cases prompt evacuation of the uterus must be resorted to. It may be suggested that if after four days' intensive glucose therapy, followed by four days of duodenal treatment, a decided improvement is not evident, then interruption of the pregnancy should be justifiable. The danger signs are a rising pulse rate, a falling blood pressure, a dry tongue and blurred vision. The daily urine output should be about 40 oz., of 1010 specific gravity.

Success depends upon instituting intensive treatment early, before dehydration has advanced too far. Laboratory investigation of the last few years, plus the brilliant results obtained through the administration of glucose in the various toxæmias, suggests more strongly than ever that some carbohydrate metabolic disturbance is at the root of the trouble.

NEPHRITIS IN PREGNANCY

Nephritis in pregnancy, which usually manifests itself during the later years of the child-bearing period, may be a very serious complication, resulting from a persistent renal or vascular disease which has reduced the renal reserve, and it may be complicated by cardiac disease, pyelitis, anaemia, thyrotoxicosis, acute infections or obstetric difficulties. The onset is insidious, often at about 5 months, and may begin with a pronounced rise in arterial tension preceding the albuminuria, and diminished output, with headache, nausea and vomiting, a sharp gain in weight, blurred vision, indigestion, epigastric pain and oedema. The essential characteristic of a true nephritic toxæmia is the frequency with which the renal function is permanently impaired (80 per cent after 3 years), each succeeding pregnancy leading to further renal degeneration and arteriosclerosis. The prognosis is grave.

Treatment.—The total urine output for twenty-four hours is measured and charted. An Esbach estimation is set up daily and the blood pressure taken morning and evening. The fluid balance is regulated. The amount of fluid by mouth is placed on a minimum or withheld entirely for the first twenty-four hours accordingly, and then given in quantity not exceeding

the total urinary output for the previous twenty-four hours. Thus the water balance is maintained by placing the level of the fluid intake at the point of maximum renal efficiency, so lessening the quantity available for oedema. The fluid balance may be maintained at the twenty ounces level and gradually increased as the output rises, forty ounces being the maximum required to meet all bodily needs. The giving of large quantities of fluids to lessen the toxæmia has been abandoned in favour of dehydrating measures, in conjunction with small fluid intake in an already water-soaked body, resulting in renal improvement and early mental restoration.

Dehydration is promoted by the giving of 50 c.c. of a 50 per cent glucose solution intravenously, repeated in 6 hours if necessary, and by purgation with $MgSO_4$, 1 or 2 ozs. daily, by the mouth, to remove the excess tissue fluids. The patient is weighed daily, and her weight checked up with the urinary output, giving the gain or loss thereby in terms of fluid. Later a salt-low diet is maintained by curtailing the use of salt at the table and avoiding salty foods. Carbohydrate metabolism requires two-thirds more water than that of protein, so that excessive carbohydrate should be eliminated, such as sugar, candy, ice-cream, honey, syrup, jelly and preserved fruits, leaving safely vegetables and starches obtainable in an ordinary diet. Strict fluid-balance treatment should be maintained throughout. Venesection may be done.

Failing reasonably rapid improvement, induction of labour by the gentlest method should be done. In the presence of a definite chronic nephritis, radical treatment is often required. It may be advisable to terminate pregnancy and prevent if possible further pregnancies, by Cæsarean section and tube resection.

LOW RESERVE KIDNEY

The low reserve kidney is a mild intoxication late in pregnancy with only slight arterial hypertension, moderate albuminuria, moderate oedema and urine of low specific gravity—a renal fatigue—in a healthy organ, temporarily insufficient functionally.

Treatment.—Dietary, with $MgSO_4$, sees the early return to full normal health. However, the time to prevent kidney strain from pregnancy is not after a chronic nephritis has become severe but while it is still mild in character or in its incipency, for then only can we hope to be of much assistance to our nephritic patients.

PRE-ECLAMPTIC TOXÆMIA

Patients with definite signs of hypertension, oedema of the extremities, headache, dizziness, blurred vision, nausea and vomiting, epigastric pain, restlessness, mental disturbances or anguish, jaundice or hæmorrhagic tendencies, together with diminished highly albuminous urine, are in this apprehensive group.

Treatment.—(See treatment for nephritis above). The total urinary output for the 24 hours is measured and charted. Daily Esbach and blood pressure estimations are made. The water balance is maintained. Dehydration is carried out with glucose and magnesium sulphate. The weight is checked daily. A spinal puncture is done, 45 to 100 c.c. are drawn off at intervals of 4 to 6 hours if no improvement occurs in 24 hours, with headaches and cerebral symptoms persisting. Venesection may be done. A salt-low diet is instituted later if the progress is favourable, if not induction or Cæsarean.

ECLAMPSIA

It has been shown that eclampsia, which is a syndrome rather than a disease, is primarily related to carbohydrate deficiency and glycogen depletion of the liver, due to foetal demands. The convulsive seizures occur at levels designated as relative hypoglycæmia, caused by the sudden rapid drop in blood sugar, it may be a few minutes' time, followed by a temporary rise, the usual physiological response of the liver to muscular convulsive activity. (Normal blood sugar is 90-120 mg.

per 100 c.c.; sometimes it drops 50 to 80 mg. suddenly). A tendency exists towards remissions to lower levels, so that the general trend of the sugar content of the blood is downward, obviously the effect of exhaustion of reserve glycogen stores in the liver.

The search for a common factor responsible for the physiological changes in the brain which may tend to precipitate convulsive seizures finds a fundamental relationship between fluid (oedema), poor oxygen supply, and the acid-base variations with their local effect on capillary circulation and permeability, and increased intracranial pressure, the control of which may be assisted by the establishment of a proper 'water metabolism'.

Treatment. Prophylactic.—Prenatal care stands out as one of the greatest contributions in the advancement of the therapy of the toxæmias. Improvement in results will come from active interference before the convulsive stage in the toxæmic patients. It is well to assume that every albuminuric or hypertension patient is a potential eclamptic who should have ceaseless watching in her prenatal period and pre-conclusive interference to prevent the convulsive phase.

Having decided by complete examination that the patient is in good health and a fit future mother, she is watched carefully for any signs or symptoms of toxæmia. Should she develop a moderate hypertension, a trace of albumin or a slight oedema, she is placed on a moderate low-meat modified carbohydrate and salt-poor diet, is given magnesium sulphate; her weight is watched; she is advised to rest several hours daily and to return at weekly intervals. If improvement is not shown (if blood pressure is 140 or over with albuminuria), she should be put to bed or hospitalized.

Nursing care.—The eclamptic patient must be treated very gently, scarcely touched at all, and the tongue protected. The utmost quiet must be observed by the nurse, who should be constantly with the patient. The patient may be blindfolded and have her ears plugged with cotton-wool, to lower her response to external stimuli and thus diminish the likelihood of further convulsions. The room should be kept dark and warm, the patient must be kept warm, even perspiring. Her position should be changed four to six times or more daily, to avoid hypostatic pneumonia, with the nose and mouth lower than the bottom of the chest. Sometimes suction or an inserted tracheal tube is used to relieve pulmonary oedema (which is often a cause of death).

Medical treatment has for its object the control of convulsions until a spontaneous delivery takes place. Better results are obtained by conservative than by more radical active interference and immediate operative delivery. A hypodermic injection of sodium-luminal, 2 or 3 grains, is given immediately, and repeated in two hours if necessary, or morphia, gr. $\frac{1}{4}$ or $\frac{1}{2}$ hypodermically, which is well tolerated, may be given, and gr. $\frac{1}{4}$ may be repeated with each succeeding convulsion until the respirations are 10 to the minute. Magnesium sulphate, 20 c.c. of a 10 per cent solution, may be given intravenously immediately after the first convulsion, and may be repeated every two hours or more until the convulsions are controlled or the blood pressure lowered. It acts as a sedative, a diuretic and detoxicant, and decreases the intracranial pressure and oedema. The magnesium sulphate may be continued after delivery, if necessary.

The symptomatic treatment of the convulsions having been accomplished by sedatives, the use of glucose is directed towards the underlying cause of the disease. At the earliest opportunity a glucose intravenous injection of 50 c.c. of a 50 per cent solution is given and repeated every 3 to 4 hours if indicated. The enormous consumption of energy incidental to the convulsions requires fuel to replace the depleted stores. The hypertonic glucose solution has a liver-sparing effect, combats the glycogen depletion of the liver, draws the fluid out of the tissues, stimulates diuresis, lessens the cerebral oedema, reduces the intracranial pressure and

thereby helps to control the severity and the number of the convulsions. It is supportive and detoxicant. Insulin may be indicated in coma or semi-consciousness or diabetics following a convulsion with low carbon-dioxide (of 30 or below), and an elevated blood sugar.

Spinal puncture is done as early as possible—complete drainage (45–100 c.c.), with the head raised at an angle of 30 degrees—and is repeated in 4 to 6 hours, failing marked improvement. Venesection of 700 c.c. or, in proportion, if the blood pressure is over 170, may be done until the pressure falls to 150. It lowers the blood pressure and assists the heart and lungs. Magnesium sulphate, oz. 2, by mouth, if practicable, is also given, to withdraw fluid from the blood reclaimed by the intravenous glucose, and thus hasten the re-establishment of body water balance. Colonic irrigations, hot packs and gastric lavage are considered.

Fluid balance.—All foods and fluids are withheld for 24 hours; then the fluid intake is given, some ounces less than the previous day's urinary output. Gradually a fluid balance is thus established and maintained on a greatly restricted fluid intake. The principles involved in the water balance of the body should receive most careful attention, as the results attendant upon it are striking.

Oxygen is given liberally, early, as a routine, by inhalation after each convulsion until breathing is normal, and continued until cyanosis disappears. It retards autolysis of the liver and aids recovery, besides acting as a cardiac nervous stimulant. Blood transfusion is given for hæmorrhage.

The temperature, pulse, respiration and blood pressure are recorded hourly. The total daily urinary output and the intake of fluids are measured, and the weight is recorded daily. An Esbach estimation is set up daily.

Diet—later, fluids, fruit juices, fruit, glucose mixture, milk, water liberally.

Rest in bed.

Sometimes small blood transfusions help or blood transfusion or serum from a recovered eclamptic. The reinfusion of autogenous washed corpuscles, with removal of the supposedly toxic plasma is reported to help. Liver extract may be given.

Interference with pregnancy may be instituted if labour supervenes; delivery should be preferably by forceps, with nitrous oxide and oxygen used sparingly, or, best, with local and spinal anaesthesia, with narcotics or ether, with as little disturbance as possible. Otherwise, labour should be hastened, and induced in the most conservative manner in all cases, just as soon as the convulsions have been controlled as otherwise, damage to the organs endangers the patient's life. Induction of labour may be accomplished by medical means, rupture of membranes, bougie, bag, version, or forceps, if no response to treatment is made. Otherwise, a Caesarean section is performed in selected cases only where urgently demanded as in the rapidly advancing case and especially in a severely ill rigid primipara with no cervical effacement where there is no response to medical treatment.

Post-partum treatment is of vital importance for the patient, who requires constant care and close observation. The diet is restricted to a proper fluid balance—dehydration by forced saline purgatives and enemas are important, with a daily check-up of the blood pressure and urinalysis.

Prognosis.—The outlook for a successful normal pregnancy in eclampsia may be less favourable than is generally supposed, but with strict antenatal care, future attempts at child-bearing need not be discouraged. The patient, however, should be carefully observed in the interval. Women with a persistent systolic pressure of 150 and diastolic above 100 at the beginning of pregnancy are not likely to go through successfully; in such, abortion must be considered. Otherwise, if a woman wishes to run the risk, rest in bed for weeks or months may be required. The behaviour of a woman's cardiovascular-renal system in pregnancy, together with

the promptness with which improvement occurs following delivery, gives to the physician a valuable hint as to what might be expected of it under subsequent strain.

Some Recent Developments in Anaesthesia

By F. B. PARSONS, M.A., M.D., M.R.C.P.

(Abstracted from *The Practitioner*, April 1933, Vol. CXXX, No. 4, p. 461)

THE BARBITURATES

THREE derivatives of barbituric acid have been used extensively as basal narcotics. These are sodium amytal, nembutal and pernocton and it is stated that they have the following points in common: (1) There may be very considerable variation in the observed effects when given in the same dose to the same species; in other words, the variability of action has made it difficult to secure an accurate scale of dosage. (2) In hypnotic doses they may produce respiratory and circulatory depression. (3) During the processes of destruction and excretion, certain products are formed which may produce mental disturbances and restlessness. These may persist during the period of excretion which may occupy several days.

Sodium amytal.—This is a white crystalline powder which is given intravenously in aqueous solution. The method of administration is peculiar; the solution is freshly prepared and is then injected at the rate of 0.1 gram per minute until the patient fails to answer to the spoken word. When the injection is completed, inhalation anaesthesia is superimposed as with avertin and both gas and oxygen or ether may be used for this purpose. Sodium amytal depresses the cardiovascular system more than avertin does; the systolic blood pressure falls to 30 mm. Hg. or more; the diastolic 15 mm. mercury or more and the pulse rate always rises considerably. Respiration is depressed to a less extent than is seen with avertin but, on the other hand, reflex excitability is at a much lower level.

Nembutal.—Nembutal (sodium-ethyl-methyl-butyl barbiturate) is more toxic than sodium amytal and therefore can be given in smaller doses to produce a similar degree of narcosis. As the dose is smaller, detoxication is accomplished in a shorter time and therefore the recovery period is not nearly so long as with sodium amytal, the recovery period of which may extend to 24 hours. This drug can be given either intravenously or by the mouth; the former method is identical with that employed for sodium amytal, but as the dose is only half as large, administration occupies only 7 or 8 minutes. When nembutal is given by the mouth an attempt is made to correlate the dose with the body weight but this does not lend itself to the accurate results which can be obtained by the former method. When given by the mouth, the patient falls asleep in about 20 minutes and there may be narcosis in a further 10 to 20 minutes. There is usually nystagmus and very frequently strabismus at this stage; an effect which is common to all derivatives of veronal in heavy dosage. There is usually some twitching of the limbs also a peculiar flickering of the eyelids. Muscular relaxation is not nearly so marked as with avertin, but there is a greater degree of insensibility. For example, when a patient has been given the appropriate dose of nembutal by the mouth, induction can be completed and anaesthesia maintained with open ether with very little change in the rate or amplitude of respiration. This function is not greatly depressed by nembutal, the only apparent difference being the decrease in the depth of respiration. The fall in blood pressure ranges from 20 to 30 mm. Hg, but this tends to rise again in a short time.

Regarding after-effects, the recovery period after oral administration is comparatively short and seldom extends beyond three hours. Not infrequently excitement occurs during this time and involuntary movements of the limbs, together with shouting may be observed.

The incidence of post-operative vomiting is no greater than with avertin. With intravenous injection Boyd states that the full hypnotic effect, when produced, lasts 4 to 5 hours and for a further 12 or more hours the patient is peacefully asleep.

O'Sullivan and Craner advise the use of nembutal and chloral hydrate as an analgesic in childbirth. Three grains of nembutal are given by the mouth followed by 30 grains of chloral hydrate. Either or both of these can be repeated in modified doses after 2 hours and additional doses may also be given. Usually a painless labour results, but this process may be prolonged and may be succeeded by restlessness.

Pernocton.—Pernocton, the last member of this series, is the sodium salt of secondary beta-bromallyl barbituric acid, and it is issued in ampoules already dissolved in water. Its hypnotic effect is comparable with that of nembutal but it is effective in smaller dosage. The average quantity of pernocton necessary to produce narcosis is 4½ grains; this amount is contained in 3 c.cm. of solution, which, when administered intravenously, at the rate of 1 c.cm. per minute, can be injected in

3 minutes and still further shortens the induction period when compared with nembutal. Administration of pernocton is conducted in precisely the same manner as with the two previous drugs and unconsciousness supervenes before the needle is withdrawn. Pernocton anaesthesia resembles that produced by nembutal, but it is stated that vomiting and excitement are prone to occur. The recovery period is said to be from two to six hours.

It is probable that nembutal is the most commonly employed barbiturate at the present time. The oral method of administration is most convenient, but it is difficult to form an accurate estimation of the necessary dose. The intravenous route gives excellent results and is preferred by many administrators, but according to the Council of Pharmacy and Chemistry of the American Medical Association it is subject to the objection that all barbiturates require large quantities of alkali for solution and, therefore, they will not remain in solution in the blood stream. They are believed to be precipitated and to circulate as foreign bodies in the colloidal state.

Reviews

ENDOCRINE MEDICINE.—By W. Engelbach, M.D., F.A.C.P., B.S., M.S., D.Sc. Volumes I, II and III with an Index Volume. Baltimore: Charles C. Thomas, 1932. Vol. I:—Pp. xxviii plus 460, with 139 figures. Vol. II:—Pp. xviii plus 473, with 109 figures. Vol. III:—Pp. xxiv plus 862, with 255 figures. Index:—Pp. vi plus 117. Price.—the whole, £10-0-0. (Obtainable from Messrs. Baillière, Tindall and Cox, London.)

THE history of medicine of the last century closed on the bacteriological note, the first quarter of the present one on the endocrine. The endocrine fashion reached its height about seven or eight years ago, and at that time there was a tidal wave of books on the subject; many of these were valuable contributions to medical literature but the great majority consisted of an agglomeration of ill-digested facts regarding the functions of the various ductless glands and of the activities of their extracts. At that time the subject was running a risk of being choked by the weeds of poly-glandular therapy, but the last few years have seen a great advance in the subject and, what is more important, they have been a period of discovery of connecting links, and of arrangement and classification.

It is therefore a good time for a book of the nature of the one under review to appear. The author is a physician and it is from the point of view of the clinician that the book is written. By this we do not mean to suggest that it is a mere record of clinical experience; far from it, the subject is treated from the beginning. After a very short but effective history of the subject there are chapters dealing with the anatomy, histopathology and physiology of the endocrine glands. There are two important chapters on endogenous and exogenous aetiology, respectively. The next section is headed 'diagnostic procedure'; it commences with a chapter of about 50 pages on anthropometry, in which the author gives a complete account of 'normal' measurements, collected from authorities in many countries. One realizes the importance of these measurements—to which he subjects all the patients in his clinic—but one also realizes that before any conclusions can be based on them it is essential to have the normals of the race with which one is dealing. The figures he quotes are mainly collected in America and under 'nationality' the commonest entry is 'native' which one concludes means the local white race stock. The next chapter heading—*anamnesis*—drove the reviewer to the dictionary where he got little help; he

soon found however that 'past history' was what he himself would have used. This section contains further chapters on case taking. The next section deals with endocrine reactions. The chapter on hormone and specific reaction is particularly useful for reference, as it contains very concise descriptions of the functions of different hormones. The first volume closes with a chapter on the relationship of endocrine disorder and public health. The author's object is to stress the dire effect of the endocrinopathies upon the health of the public and to point out that defects in the endocrine system are amongst the most important causes of human incompetency and delinquency. There are in the next two volumes four similar chapters dealing with this same subject in specific relationship to these disorders at the four different age periods.

Space will not permit of any detailed discussion on the next two volumes. They contain four sections, respectively, on infantile, juvenile, adolescent and adult 'endocrinopathies'. There are in all four volumes—the fourth being devoted to a bibliography and indexes of names and subjects. The whole provides as complete a treatise on the subject of the endocrine glands and their disordered functions as one could want. It is encyclopedic as regards the volume of the information it contains, but it does not suffer the disadvantage of having been written by a number of authors whose ideas are not in tune.

The book is singularly free from what the English reader calls 'Americanisms'. 'Incretion' and 'incretory' are no longer new and are justifiable shortening of 'internal secretion' and its adjectival form. The reviewer was inclined to protest against 'hyposectomized', until he decided that it was a misprint (the only one he saw) for 'hypophysectomized'. The illustrations and diagrams are abundant and always useful. The reproduction of the skiagrams and histological sections are particularly good. We have two small criticisms here; the author has written the indicating letters (*e.g.*, C, cortex; M, medulla) on the photographs and in some instances it is more difficult to find the letter than it was to 'find the girl's father' in the old Christmas cracker puzzle. Also the diagram on page 144 is a little too 'kindergarten' for a book of this kind.

We cannot conclude without congratulating the publishers on their share in the production of a work that is of the highest order from a scientific, from a practical, and from an artistic point of view.

L. E. N.

SEX AND INTERNAL SECRETIONS. A SURVEY OF RECENT RESEARCH.—Edited by E. Allen. London: Baillière, Tindall and Cox, 1932. Pp. xxii plus 952, with 318 figures. Price, 57s. 6d.

The publication of this volume celebrates the tenth anniversary of the beginning of an inquiry into the problems of sex initiated by the Bureau of Social Hygiene and carried out under the control of the Division of Medical Sciences, National Research Council of America. As these researches are still being conducted the book under review is in the nature of an interim report and general summing up of the state of our knowledge on sex up to the present day.

There are nineteen chapters to which twenty-two authors have contributed, most of these hold important university appointments in the United States, and are actively engaged in research along one or more of the lines touched on in the book.

In a book compiled in this manner there is a good deal of overlapping and repetition in certain of the chapters. To some extent this is unavoidable, but it is felt that if the editor had exercised his authority a little more, and cut out some of these repetitions, it would have been an advantage.

The title of the book is somewhat misleading for it is much wider in its scope than this indicates, and several of the chapters make no reference to internal secretions at all. It appeals to the reviewer much more as a general summary of the whole subject of genetics than one limited to the influence of internal secretions on sex, and as such it will be of great value to all biologists. The mass of papers that have been consulted is enormous and the extent of the search through the literature is shown by the long bibliography after every chapter.

This publication cannot fail to be of great assistance to any one engaged on problems relating to breeding of animals, because references to all the recent work on the subject are to be found somewhere in the book, and this subject has now become so many-sided and so complicated that without a book of reference of this type it would be difficult to progress, because it would be far beyond the powers of one man to keep abreast of the literature.

Although it may be read with profit by those with only a general interest in biology, it is much more to be recommended as a book of reference to the specialist, for he will find discussed within its pages whatever problem in genetics he may be working upon, or if it is not fully discussed he will be given all the references he will require whereby to follow up his special inquiry.

P. A. M.

RECENT ADVANCES IN RADIUM.—By W. Roy Ward, M.B., B.S., M.R.C.S., and A. J. Durden Smith, M.B., B.S., M.R.C.S. London: J. & A. Churchill, 1933. Pp. viii plus 324, with 4 coloured plates and 140 black and white illustrations. Price, 21s.

THE Recent Advances series has acquired a very high reputation and this latest addition will most certainly help to maintain it. However, except in the matter of quality, this book differs from the others of the series very markedly; the excuse for the title and the justification for the procedure the authors have adopted are the same, namely, that the whole subject of radium therapy is so new that everything worth knowing on the subject is necessarily a recent advance. Consequently, the book is nothing less than a textbook on radium therapy, and a reader who has hitherto enjoyed complete ignorance in this matter need not fear being landed in the middle of a subject where he will be completely lost; on the contrary, if he opens the book at the beginning he will find the mystery of radium and its therapeutic properties slowly unravelled in a manner that would throw no burden on even a very mediocre intelligence.

The book is divided into three parts; the first part deals with the fundamentals of radium, its physics, its

selective action, the radio-sensitivity of different tissues and cells, the measurement of dosage, radium apparatus, protective measures and so forth; the second part deals with the treatment of malignant tumours in different parts of the body, region by region; and part three deals with the treatment of non-malignant tumours, and other conditions, such as uterine hæmorrhage.

The most important lesson the book conveys is that there are very great potentialities in this form of therapy, but that it will take many generations of essentially experimental clinical trials and most laborious appraisement of the results before we can hope to gauge the extent of its possibilities or to give any accurate prognoses in individual cases, but that even at the present day we have reached a stage where radium therapy should always be considered when the treatment of any operable or inoperable new growth is under consideration, and that there are certain other conditions in which it is the best form of treatment at present known to science.

There are numerous very useful illustrations distributed throughout the book; the microscopic sections are particularly well reproduced; and there are many coloured plates. A number of before-and-after photographs are included, but these provide their own justification and, though mostly, if not all, taken from the authors' personal experience, the claims they make for good results are so entirely impersonal that one's natural prejudice against this form of illustration is entirely overcome.

We can strongly recommend the book to all medical men; if they are not particularly interested in the subject now, they probably will be when they have read this book.

GENERAL HÆMATOLOGY WITH SPECIAL REFERENCE TO THE CHILD IN HEALTH AND DISEASE.

—By W. M. Feldman, M.D., B.S., M.R.C.P. (Lond.), F.R.S. (Ed.). London: John Bale, Sons and Danielsson, Ltd., 1933. Pp. 96. Illustrated. Price, 2s. 6d.

THIS series might well be called the vest-pocket monograph series, as compared with other 'pocket' series it really is very small. However the print will not be found at all trying to most readers, and in these days of large volumes it is very pleasant to have a light book in one's hand.

It was of course impossible to write a treatise on such a large subject in the small space available, and it is rather difficult to say what the author has exactly achieved. It is not a book on technique, as this is given no place, and it is not a book on blood diseases; it might be described as a student's primer on the applied physiology of the blood. There is in it much useful information very clearly expressed.

The author does not appear to have accepted the recent work on pernicious anæmia as he makes frequent reference to the excessive hæmolysis in this condition and, at least on one occasion, to toxins as the cause of this.

The book should be valuable to the student, or even the nurse, reading for an examination.

L. E. N.

BLOOD PICTURES: AN INTRODUCTION TO CLINICAL HÆMATOLOGY.—By C. Price-Jones, M.B. (Lond.). Third Edition. Bristol: John Wright and Sons, Ltd., 1933. Pp. 72, with 5 coloured plates and 7 illustrations in the text. Price, 6s. 6d.

THE name 'Price-Jones' has acquired a very firmly-established place in hæmatology. This little book of his is perhaps not so well known as the author.

It is a book for the student and general practitioner and the intending reader need not be frightened by the prospect of a volume full of curves and mathematical calculations; the book contains nothing of the kind. Price-Jones curves are given, but the whole subject of cell measurement occupies only four pages. The book is what its name suggests. Simple technique is

described and there are some very useful plates. As a small point of criticism, in the reviewer's opinion all coloured plates of blood pictures should have on the plate itself some indication of the staining method used; that this is clearly stated in the text is no answer to this criticism.

The plates are well reproduced and the general format of the book is good. It should be useful to students and general practitioners.

L. E. N.

CLINICAL OPHTHALMOLOGY FOR HOUSE SURGEONS AND STUDENTS.—By J. M. Bickerton, M.A., B.Ch., F.R.C.S., and L. H. Savin, M.D., M.R.C.P., F.R.C.S. London: H. K. Lewis and Co., Ltd., 1933. Pp. 158, with 92 illustrations including 6 plates. Price, 7s. 6d.

THIS small book has been produced with the object of providing a short course of instruction for students, because the standard textbooks are all so large.

The authors have admirably succeeded in the task they have set themselves for they have presented the subject in an eminently practical manner only giving the essentials. The book might well be used to replace the notes the student usually tries to take while attending his practical ophthalmology classes, and, being properly arranged and carefully edited, it is much more useful than the most carefully taken notes can ever be. The low price also brings it within reach of all. The penultimate chapter is devoted to formulæ which will cover the whole field of eye therapeutics in any average practice, and the last chapter is devoted to drawings of all the common eye instruments. Provided it is not looked upon as a textbook but simply as an introduction to the study of ophthalmology, it can be confidently recommended to all beginners.

MEDICINE FOR DENTAL STUDENTS.—Edited by H. A. Lucas, Edinburgh: E. & S. Livingstone, 1933. Pp. 208. Publishers:—Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 5-10.

THE recent inclusion of an examination in medicine for the L.D.S. Eng. has made the subject of medicine of more than academic interest to the dental student. This book is a laudable attempt to provide him with the essentials of the subject.

In the preface the editor wisely remarks that ordinary textbooks of medicine fail from the point of view of dental students in being too long, while they contain too little pertaining to those special aspects of medicine which are of importance to the dental student. It is in this latter respect that this book must be tested. Twenty years ago dentistry was mainly affiliated to surgery, partly because of the part which the College of Surgeons played in sponsoring the L.D.S. and partly because the obvious extensions of dental conditions were into the domain of surgery rather than medicine. But at the present time some knowledge of medicine is almost of equal importance. The whole problem of focal infection in relation to many conditions, medical rather than surgical, make it necessary for the dentist to know something of the conditions which may be caused by dental infection. Again, such diseases as purpura, jaundice, leukaemia or agranulocytosis, which may give rise to oral infection and thus come under the notice of the dentist, have assumed a practical importance in dental surgery. The increasing use of local anaesthesia has made a knowledge of cardiac and respiratory conditions essential.

The book opens well with two chapters on infection and immunity. Then follow chapters dealing with the different systems of the body. These are of necessity brief and in some cases too brief. Thus the chapter on diseases of the blood only extends to ten pages. Yet in this section are included conditions of such practical importance as leukaemia, purpura hæmorrhagica and hæmophilia. In leukaemia, for instance, a stomatitis is of frequent occurrence. In the past it has happened that patients have been seen by the dentist with what

appears to be an ordinary type of stomatitis. The extraction of teeth has been followed by an intractable hæmorrhage resulting in death. This is a section which should be amplified considerably, and we hope that in future editions the opportunity will be taken to emphasize even more than has been done, those particular aspects of medicine which are of practical importance in dental surgery. Though brief, this book should fill a useful place and prove of much assistance to the student in preparing for his examinations.

E. H. B.

THE HISTORY OF DERMATOLOGY.—By Wm. A. Pusey, A.M., M.D., LL.D. London: Baillière, Tindall and Cox, 1933. Pp. xviii plus 224, with 32 illustrations. Price, 17s. 6d.

THIS is the first history of dermatology to appear in the English language, and as such it cannot fail to be of interest to all English-speaking medical men.

Like most histories on medical subjects it begins with the Edwin Smith papyrus, as this is the earliest written record extant dealing with medical science, and it is surprising to learn that both in this and in the famous Ebers papyrus considerable space is devoted to dermatology. It seems that the cosmetic side of the subject received more attention in those ancient days than the actual treatment of diseases though these also received attention. We also learn that among the remedies used for treatment of skin diseases 1,500 years B.C. calamine and sulphur occupied an important place.

The book is divided into chapters each of which covers a definite period of history, and, written as it is by a man who has devoted his life to the study of skin diseases and has contributed a great deal to the literature, the value of each advance is accurately gauged with the result that the complete record gives an impression of careful balance, as every noted dermatologist from Galen to Hebra receives the proportionate amount of attention to which his work entitles him.

The early chapters in which the work of the great dermatologists of the past is described are more interesting to read than are the chapters devoted to our contemporaries, but this is probably unavoidable because it is notoriously difficult to write current history on any subject. The book is, however, a valuable contribution to the history of medicine and the author is to be congratulated on the admirable performance of a difficult task. The paper, printing, binding, and the manner in which the well-selected illustrations have been reproduced, combine in the production of an artistic volume, which quite apart from the interest of its contents will be an ornament on the shelves of any library.

P. A. M.

MEDICAL ENTOMOLOGY.—By R. Matheson, Ph.D. London: Baillière, Tindall and Cox, 1933. Pp. xiv plus 489; 211 figures. Price, 29s.

THIS general textbook on medical entomology deals mainly with American insects and has therefore definite limitations as a universal textbook. The structure and natural history of the insects described is clearly and concisely recorded, but the epidemiology and the practical measures for control of some of the diseases transmitted by insects are very incomplete, especially the chapter on malaria control. The importance of dense shade as an anti-malarial measure, and the dangers attending drainage in certain parts of India appear to be unknown to the author; likewise the exact method by which petroleum oils destroy mosquito larvae.

On page 22 the lung fluke, *Paragonimus westermani*, is stated to occur in Assam and Bengal. The reviewer is unaware of any cases ever having been recorded in either of these two provinces of India.

Reference is made to the pioneer work of Knowles, Napier and Smith on the problem of kala-azar transmission with *Phlebotomus argentipes*, but the actual reference is not given although the book has otherwise

a very excellent index to authors and a well compiled subject index.

The anatomical sections are well illustrated, most of the illustrations being original.

The book is well printed and an introductory chapter gives an excellent brief account of the history of medical entomology during the past fifty years.

G. C. R.

HYGIENE FOR NURSES.—By John Guy, M.D., D.P.H. (Camb.), F.R.F.P. & S. (Glas.), F.R.C.P. (Edin.), and G. J. I. Linklater, O.B.E., M.D., D.P.H., D.T.M. & H., M.R.C.P. (Edin.). Second Edition. Published by Messrs. Butterworth and Co. (India), Ltd., Calcutta, 1933. Pp. xi plus 211. Illustrated. Price, Rs. 3-12.

DRS. GUY AND LINKLATER bring to the task of writing a book on hygiene for nurses not only a wide practical knowledge of public health but also invaluable experience gained as examiners in hygiene to the General Nursing Council.

In accordance with the modern tendency to lay emphasis on the importance of individual hygiene as opposed to environmental hygiene, about two-thirds of the book deals with the former. After dealing with the general aspects of personal hygiene, the hygienic requirements of special groups, the new-born, the school child, and the elderly are considered. The section dealing with foods and metabolism is up to date and the methods of working out diet values in particular is excellent. Instructions for the control of communicable diseases and parasites are adequate, but the nurse without a good working knowledge of the infectious diseases will get no help from the book for recognizing the symptoms of onset, and may fail therefore to advise precautionary measures at a time when they will be most useful.

The account of ventilation, heating, lighting, sewerage and water supply is clear and concise, and the nurse will acquire from it with ease all the requisite knowledge for 'transforming each home which she visits into as hygienic a state as possible'.

The book is written primarily for nurses taking the general nursing certificate and as the whole bias of training is towards the cure of sickness, the nurse is apt to fail to appreciate the preventive aspect. This little book on the 'science of health and its maintenance' will supply an excellent introduction to the wider aspects of her duties.

There are one or two errors, e.g., in the percentage of CO₂ in air on page 129 and in the law relating to the notification of births on page 197, and the explanation of convection on page 134 is rather difficult to follow, but these are minor defects and do not seriously depreciate the value of an otherwise useful little book.

Correspondence

THE TREATMENT OF ACNE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to Dr. P. H. Bhatt's letter (published in the May issue of your journal, page 302), asking for suggestions in treating a case of acne vulgaris, I would like him to try about twenty injections (intravenous) of calcium chloride or calcium gluconate (5 to 10 c.cm. of 10 per cent solution), in addition to local treatment recommended by Lieut.-Col. Acton.

It is stated that injections of calcium chloride cause disappearance of almost all papules and pustules in some cases, and marked improvement in many of them with diminution of the oiliness of the skin and even the disappearance of comedones.

Yours, etc.,
S. R. INGLE,
Medical Officer.

MIRAJGAON, AHMEDNAGAR DISTRICT,
13th June, 1933.

THE INTERNATIONAL POPULATION UNION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have been trying for some time to organize a National Committee of the International Population Union in India. I think population problems are of such importance in India that an organization of this kind can do very useful work. I succeeded in getting the Indian Economic Association interested in this

question and at their last annual meeting they appointed a committee consisting of Dr. Radhakamal Mukerji of the Lucknow University and myself to report on the feasibility of starting a National Committee in India and to suggest the lines on which it should be organized. A committee of this kind cannot, of course, be confined to economists alone. I shall, therefore, consider it a favour if you would bring this proposal to the notice of medical men through your *Gazette* and ask those interested in this matter to communicate with me.

My idea at present is that the national organization should be an independent unit but should work in close co-operation with the other learned societies of India, like the Indian Science Congress and the Indian Economic Association. I do not know if there is a medical association of this kind but if there is its co-operation will be welcome.

As regards the International Population Union, they are quite willing to recognize a national association. I am going to England and I hope to obtain from them the conditions on which affiliation as a national unit in the International Union would be given to the Indian Association. The terms will be communicated to persons interested in this proposal after my return at the end of September.

Yours, etc.,
DR. B. N. KAUL,
Chairman, Economics Department.

ALIGARH MUSLIM UNIVERSITY,
ALIGARH, U. P.,
3rd June, 1933.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL C. A. SPRAWSON, C.I.E., V.H.S., is appointed Honorary Physician to The King, *vice* Colonel W. H. Leonard (retired), 12th February, 1933.

Colonel H. R. Nutt, V.H.S., Inspector-General of Civil Hospitals, United Provinces, was appointed to officiate as Surgeon-General with the Government of Bombay, with effect from the 29th March, 1933.

Lieutenant-Colonel M. S. Irani, Superintendent of Matheran, to officiate as Civil Surgeon, Nasik, in addition to his own duties, *vice* Mr. A. D'Silva.

Lieutenant-Colonel R. G. G. Croly, Professor of Surgery, Medical College, Madras, is appointed to officiate as Surgeon-General with the Government of Madras, *vice* Major-General C. A. Sprawson, C.I.E., V.H.S., granted leave out of India.

The services of Major H. J. Rice, M.C., and Captain T. J. Davidson are placed temporarily at the disposal of the Government of Burma, with effect from the date on which they assume charge of their duties.

Major B. Z. Shah on his return from leave to officiate as Civil Surgeon, Dharwar, with attached duties, *vice* Mr. D. S. Dhavle.

The services of Captain R. D. Alexander are placed temporarily at the disposal of the Government of Madras, with effect from the 3rd April, 1933.

The services of Captain A. Tait are placed at the disposal of the Government of Bombay, with effect from the afternoon of 12th June, 1933, for appointment as officiating Superintendent, Central Mental Hospital, Yeravda.

The services of Captains F. E. B. Manning and W. Lawie are placed temporarily at the disposal of the Government of the United Provinces, with effect from the date on which they assume charge of their duties.

To be Captain (on probation)

B. N. Khan, 24th April, 1933.

To be Lieutenants (on probation)

Said Ahmad.

C. C. Kapila.

W. M. E. Anderson, 24th April, 1933, and remains seconded.

R. D. Scriven, 28th April, 1933.

LEAVE

Major-General C. A. Sprawson, C.I.E., V.H.S., Surgeon-General with the Government of Madras, is granted leave out of India on average pay for 2 months and 2 days combined with leave on half average pay for 19 days, with effect from the 14th July, 1933.

Lieutenant-Colonel A. D. Stewart, Director, All-India Institute of Hygiene and Public Health, Calcutta, is granted leave on average pay for 2 months, with effect from the 15th July, 1933. He was permitted to prefix the holidays on 14th and 15th April and the Institute vacation from the 16th April to the 14th July to the leave.

Major E. C. A. Smith, Superintendent, Central Mental Hospital, Yeravda, is granted leave on average pay for 8 months followed by leave on half average pay for 4 months, with effect from 6th June, 1933, or subsequent date of relief.

PROMOTIONS

The provisional promotion to the rank of Captain of the undermentioned I.M.S. officers is confirmed, subject to His Majesty's approval:—

A. M. Fraser.	G. K. Graham.
M. H. Shah.	A. W. West.
J. R. Dogra.	A. B. Guild.
S. Narain.	Dev Datt.
M. G. Saincher.	R. T. Hicks.
B. L. Taneja.	

Lieutenants to be Captains

F. M. Sewell. Dated 7th March, 1930.

W. Fleming. Dated 22nd May, 1933. (After forfeiting 3 months' service for promotion.)

Lieutenants (on prob.) to be Captains (on prob.)

S. W. H. Askari. Dated 3rd January, 1933.

D. P. Nath. Dated 21st May, 1933.

Captain E. G. Michelson forfeits 12 months' service for purposes of promotion. Dated 4th January, 1933.

Captain G. J. Smith forfeits 6 months' service for purposes of promotion. Dated 24th September, 1932.

Lieutenant W. Fleming forfeits 3 months' service for purposes of promotion. Dated 31st July, 1931.

RETIREMENTS

Lieutenant-Colonel W. E. Brierley retires, 8th April, 1933.

Major M. Murphy, M.C., retires, 22nd May, 1933.

Notes

THE 42ND CHEMISTS' EXHIBITION, LONDON

THIS Exhibition will be held this year from 25th to 29th September in the New Hall of the Royal Horticultural Society, Westminster, S.W. It has been organized on much the same lines as in previous years, and will give the chemist an opportunity of seeing all the newest appliances and drugs that he deals with in his profession. The management, as hitherto, is pleased to welcome visitors from the Dominions and Colonies, and such gentlemen will be admitted on presentation of business cards.

ATEBRIN-PLASMOQUINE

MESSRS. HAVERO Trading Company, Ltd., the sole importers of the above well-known antimalarial drugs, are glad to announce that on account of the steadily increasing demand for plasmoquine, they have been able to reduce the prices of the current trade packings of all plasmoquine preparations by 25 to 30 per cent.

The reduction of Atebrin prices is, however, less striking as the company continues to pay a 30 per cent customs duty for this drug.

A list showing the new prices can be had on request.

THE RISKS OF LIQUID MILK

(Reprinted from the *Medical World*, 27th March, 1931)

IN these days when lactation is fast becoming a lost art the most responsible task facing the general practitioner is the due selection of an artificial food; if he gives mistaken advice he is certain to be reviled for every juvenile complaint that maternal solicitude ascribes to its use for many a day after. Moreover, when the doctor adds to her toilsome duties by stopping her simple drafts on the fount of Nature, the mother must exchange her milk, warm, sterile and amphoteric, for an elaborate concoction based upon cow's milk, of uncertain source and even if carrying an official guarantee probably defiled in domestic storage unless heated to a degree destructive of nutritive properties.

But both the doctor's responsibilities and the mother's toils may be discounted entirely by the use of a simple preparation of standard composition such as the COW & GATE milk food. It is unnecessary to repeat how greatly the composition of milk varies on account of a number of causes: the feeding of the cow, the source of the supply, and, above all, its accidental pollutions. Notorious also is the contamination to which it is exposed in the course of distribution—the transfer to household vessels, and even when bottles are supplied, their rapid infection while awaiting refilling. In short, there is no safety in a fluid which is the most admirable culture medium known, and to which no amount of 'grading' ensures its bacterial innocence. With Cow & Gate milk foods the whole picture is changed. Of uniform composition at all times, when reconstituted with pure water only, it represents a super-grade milk free from all impurities.

METRI-CAUTERY FOR INFECTED CORNEAL ULCERS

By A. CHRISTIE REID, M.D.

THE instrument shown in the accompanying figure, made for me by Messrs. Down Bros., is an improvement on the design of Professor Passow, and has proved invaluable, (a) in arresting septic corneal ulcers that have not yet developed hypopyon; (b) in checking the progress of severe hypopyon ulcers and leaving, even in advanced cases, a very moderate scarring, allowing sometimes a most surprising degree of vision.

The point should be heated from the main electric supply till the thermometer registers 70°C.; it should not be applied over 85°C. A gentle stroking of the surface of the ulcer for a few seconds usually suffices. The process may be repeated later if any fresh advance is noted, but then, as a rule, only to the advancing edge.

The instrument has proved in my hands much less damaging than the actual cautery, even at a dull red heat and by the 'approach' method, that is, not touching.

TREATMENT OF TUBERCULOSIS WITH OILY SUSPENSIONS OF GOLD

In a recent communication to the International Tuberculosis Conference at the Hague Drs. F. Dumarest and H. Mollard report as follows:—

'For the last six years we have been occupied in studying the treatment of tuberculosis with gold. During the last eighteen months we have been led to investigate in particular the use of gold compounds suspended in oil. What was the starting point of our trials and what were their first results?

Impressed by the numerous and often serious secondary effects observed by our predecessors in the field of chrysotherapy, we first of all commenced with the administration of minute, almost homeopathic

doses. We believed that the danger of gold salts consisted in their toxic effect on the organism.

We found, however, that the small doses gave us only a very small percentage (12 per cent) of radiologically demonstrable improvement and the secondary complications of the treatment remained frequent. We then experimented with the administration of higher doses, even giving as much as 1 gramme per week. We observed two facts. Firstly, the frequency of improvement in the patients was much increased. The number of cases developing toxic symptoms became neither more nor less numerous.

This study permitted us to draw two conclusions: the higher doses were incomparably more efficacious than the small doses. The secondary complications were independent of the dosage and were rather a sign of intolerance than of intoxication.

The problem, therefore, was to inject as large a dose as possible and at the same time to increase the tolerance of the patient. At this stage, on the advice of our colleague, Dr. Feldt, and by analogy with certain forms of anti-syphilitic therapy, we conceived the idea of preparing oily suspensions of gold.

Theoretically oily suspensions have two advantages over aqueous solutions:

I. *They are better tolerated by the patient* on account of the slow rate of absorption of the medicament, which must cross over two thresholds before reaching the blood, i.e., that of the oil and that of the muscle cells. Not only is it delivered drop by drop into the circulation, but between the time of making the injection and the moment when the last drops enter the organism a period of 4—8 days elapses. The organism is thus provided with a supply of the product which is absorbed very slowly. Thus there is no violent shock and the body gradually becomes accustomed to the preparation.

II. *The action of the suspended substance is prolonged.* The injected material only accomplishes its voyage through the body little by little. When the first particles are being excreted in the urine and the faeces, other particles are still present in the muscle at the site of injection. The organism thus remains under the influence of the product as long as this metabolic process lasts. The action of the medicament is continuous instead of transitory.

On this theoretical basis we prepared a 20 per cent solution of 'Solganal-B' (aurothioglucose) in almond oil, which we injected three times a week in almost constant doses. At first we gave three injections of 0.2 gramme of the gold compound, then three injections of 0.3 gramme, after which we continued to inject 0.4 gramme till the end of the course, i.e., 12 grammes per week until 8—10 grammes in all had been given.

To-day we are able to present the results of these three experiments:—

I. *The method of injecting small doses in aqueous solution* produced a radiologically demonstrable improvement in 12 per cent of cases, and secondary toxic effects were observed in 60 per cent.

II. *Treatment with higher doses but still in aqueous solution* produced improvement in 52 per cent of cases and slight or severe complications in 60 per cent.

III. *Still larger doses but in oily suspension* produced rapid improvement in 60 per cent of cases and slight secondary symptoms in 39 per cent.

So much for quantitative results. Qualitatively we observed that with oily suspensions the success of treatment was more rapid and more often complete than formerly. More important still, any secondary symptoms observed were slight, transitory and in no case prevented continuation of treatment after a brief interruption.

Further, we would add that many cases who did not tolerate small doses in aqueous solution supported large doses of the oily suspension without any signs of intolerance and with highly beneficial results.

Our experiments, therefore, completely confirmed the theory on which our researches were based. What practical conclusion can we draw from them? This

method, which we have applied personally to a large number of patients, has two chief indications; it increases tolerance and is, therefore, particularly suitable for fragile patients who are highly susceptible to gold, and for patients who tolerate the aqueous solution badly. It enhances the action of the gold compound and is thus especially suitable for patients who are resistant to the ordinary forms of gold therapy.

THE BURROUGHS WELLCOME AND CO. EXHIBITS AT THE CHICAGO EXPOSITION

THE exhibits represent the most recent steps towards ideal therapeutic, dietetic and pharmaceutical preparations. The fixed policy of this firm is never to rest upon laurels already gained, but to press forward constantly to a higher standard of attainment. The steady pursuit of this policy has established amongst professional men throughout the world a confidence in the firm's products which is a reward in itself.

Burroughs Wellcome and Co. are the successors to, and sole proprietors of, the business of Brookedon, who originated compressed medicines in the shape of bi-convex discs. They have pioneered the development of compressed medicaments under their trade mark names 'Tabloid' and 'Soloid' by means of specially-devised machinery, invented and produced at great cost and working with the precision of fine watch-work.

By its aid, under the direction of specially-trained chemists and pharmacists of long experience, compressed products of unique accuracy of dosage, perfection of finish and supreme reliability are produced.

By combining research with industry, pioneer preparations of scientific certainty have been produced, which have replaced the uncertain, unreliable pharmaceuticals of former years. Some of the results of scientific research are the production of drugs, such as 'Diginitin' and 'Ernutin', which replace their uncertain predecessors—tincture of digitalis and extract of ergot. Other examples of the firm's pioneer work are exhibited.

Special attention is devoted to the production of fine chemicals and galenicals of outstanding purity and to the preparation of animal and vegetable medicinal substances of definite strength and activity. The Wellcome materia medica farm assists materially in maintaining supplies of medicinal plants of a high standard of quality.

As pioneers in the supply of medical outfits of high quality and compactness for the use of physicians, surgeons, explorers and travellers, Burroughs Wellcome and Co. have a world-wide reputation. The exhibits include historical medical equipments of the most celebrated pioneers of travel. 'Tabloid' equipments are the only medical outfits to have been carried to the North and South Poles by land, sea and air.

Pioneer research

Burroughs Wellcome and Co. have pioneered the introduction of many new and valuable natural medicinal agents, notable amongst which is *Strophanthus Kombé*, the powerful African arrow poison which has proved so valuable in certain heart disorders.

Sir Thomas Fraser, of Edinburgh University, first investigated and demonstrated the properties of *strophanthus* from a comparatively small specimen, and Burroughs Wellcome and Co. immediately took vigorous steps to procure supplies.

Emissaries were sent to collect the small reserves of arrow poison from the rude huts of many Central African warriors. In this way a fair quantity was accumulated, but at a cost of more than £20 per pound.

These earliest supplies were obtained quite regardless of monetary considerations and, notwithstanding the great cost, parcels of this medicinal agent and its preparations were at once distributed, without charge, to leading physicians throughout the world. By this means the therapeutic properties of *strophanthus* were confirmed by investigators in various lands.

In the treatment of leprosy with esters of acids of the chaulmoogric series, 'Moogrol' has been used in leper colonies throughout the world, and was the result of years of patient investigation and clinical trial. The addition of iodine markedly reduces the irritating property of the ethyl esters, and preliminary clinical evidence obtained with iodized 'Moogrol' has confirmed this.

In the dietetic field, 'Dexin' High Dextrin Carbohydrate marks the outcome of researches conducted in the Wellcome Experimental Research Laboratories, New York.

Ergotoxine—an alkaloid of powerful action in contracting the blood vessels, and isolated owing to the initiative of Burroughs Wellcome and Co. 'Ernutin' is a clear solution presenting ergotoxine—together with 'Ergamine' and 'Tyramine'—in definite amount and in a state of chemical purity. 'Ernutin' (Oral) contains 0.033 per cent and 'Hypoloid' 'Ernutin' 0.1 per cent of ergotoxine ethanesulphonate. 'Ergamine' and 'Tyramine' are organic bases present in ergot.

Alkaline medication

It is difficult to persuade patients to persist in the treatment when sodium bicarbonate and similar alkalis are prescribed in the ordinary way. It is also noted that the psychological effects of such simple prescriptions are not good, and no single alkaline base can secure remineralization of the system, which is often necessary.

'Tabloid' 'Alvesen' solves these difficulties. One in a glass of water produces a very acceptable effervescent draught; the equivalent of 25 doses is contained in a tube; each product presents the alkali bases—sodium, potassium, magnesium and calcium—in precise amounts.

Iron

Because of its hæmatinic value, iron, alone or in combination, is the therapeutic agent most usually employed in conditions of blood deficiency. Iron is conveniently prescribed in the form of Bland Pill.

The therapeutic value of Bland Pill depends upon the presence of iron carbonate in the ferrous state, but in ordinary forms of Bland Pill there is great danger that this ferrous carbonate will be more or less oxidized to the irritating and astringent ferric salt.

The problem of securing the certain administration of ferrous carbonate in an unoxidized condition has been solved by the introduction of 'Tabloid' Bland Pill.

In this product the precise proportions of ferrous sulphate and alkaline carbonate are intimately associated in such a manner that interaction is prevented until the product is administered.

In the stomach, however, the interaction takes place and ferrous carbonate is formed. This fact is sufficient to account for the great superiority of the 'Tabloid' product. It is perfectly stable and permanent until it comes into contact with the gastric secretion.

Ephedra—Ma Huang

Ephedra—known to the Chinese as Ma Huang—is the source of one of the latest additions to our materia medica—the alkaloid ephedrine. Investigation proves that there is great variation in the ephedrine content of different species of ephedra, and that some are practically devoid of activity.

Ephedrine hydrochloride is prepared at the Wellcome Chemical Works, Dartford, Kent (Eng.), elaborate precautions being taken to secure purity, particularly in regard to freedom from pseudo-ephedrine and other subsidiary alkaloids, of which *l*-methyl-ephedrine and *nor-d-ψ*-ephedrine were discovered in Ma Huang by Burroughs Wellcome and Co. Standardization by chemical means ensures uniformity of composition and therapeutic activity.

CAPROKOL

ALTHOUGH it is only a few years since Caprokol was issued, its administration in cases of diseases of the urinary tract has been followed by such striking results that within this comparatively short time its use in the treatment of such diseases has become world-wide.

Caprokol possesses also other properties which are of special value in a urinary antiseptic. For instance, it is chemically stable, non-toxic, non-irritating, analgesic, rapidly bactericidal in high dilution, highly penetrating, active in the presence of organic matter, and free from objectionable odour.

The advantages of these properties in an orally-administered urinary antiseptic are obvious; particularly so is the remarkable fact that such a powerful antiseptic is non-toxic and non-irritating to the mucous membrane of the bladder and of the urethra.

To obtain the maximum benefit from Caprokol treatment, therefore, it is necessary to maintain a uniform concentration of Caprokol in the urine, and, at the same time, to avoid any other form of treatment that is calculated to increase the surface-tension of the urine. Both of these conditions can be secured without difficulty. In order to maintain the normal concentration of Caprokol in the urine it is necessary merely to administer the capsules regularly at the rate of 9 to 12 capsules per diem according to the nature of the infection under treatment, avoiding dilution of the urine by an excessive intake of liquids; in the meantime the surface-tension of the urine can be maintained at a minimum if the precaution be taken not to administer those substances which are known to increase the surface-tension of liquids in which they are dissolved. Examples of such substances are bicarbonate of soda, nitrates and diuretics generally. In this connection it is important to note that mere dilution with water also increases the surface-tension of urine, apart from the fact that the addition of water increases the dilution of the antiseptic; thus for two very good reasons '*forcing fluids*' as commonly employed in the treatment of diseases of the urinary tract should not be administered simultaneously with Caprokol, as this method of treatment, as well as that of treatment by diuresis, obviously tends to defeat the object of the antiseptic therapy.

If the physician is of the opinion that a specific case is one which needs to be treated by diuresis or with '*forcing fluids*' such treatment should be undertaken before the Caprokol administration is started; in no circumstances should two forms of treatment be undertaken simultaneously. If these precautions are observed the results of Caprokol treatment will be uniformly successful, for there is no condition in which Caprokol is contra-indicated.

It is very important to note that in order to ensure permanently satisfactory results from the administration of Caprokol the treatment should be persistent in all circumstances. It is just as important to continue the treatment in cases where an immediate response is observed as it is in cases where the response is not apparent for some time. In other words, on no account should the treatment be abandoned in the early stages either because of apparent cure or of apparent absence of response.

The administration period obviously depends upon the nature of the infection. For instance, in cases of pyelitis and cystitis due to micrococci such as staphylococci and streptococci with no *B. coli* infection the administration of nine capsules *per diem* generally produces sterile urine within two or three weeks from the start of the treatment. If the infection be due to *B. coli* more persistent treatment is necessary; but, except in very rare cases where the infection is an overwhelming one, even this infection will succumb to Caprokol treatment eventually.

In most *B. coli* infections, however, the usual local treatment is advised at first in order to reduce the number of organisms in the early stages. When this reduction is accomplished Caprokol can be relied upon

to produce a completely sterile urine. To effect this, it may be necessary to administer as many as twelve capsules a day, and to persist in the treatment for sixty or ninety days or even longer; eventually, however, complete sterility usually will be effected.

GADIL CALCIC WASSERMANN

GADIL CALCIC is a modification of the well-known remedy 'Gadil' prepared by the Wassermann Laboratories; it is said to be a combination of organic salts of calcium, synthetic guaiacol, menthol, eucalyptol, lecithin, the vehicle being cod-liver oil. It is indicated in the treatment of all tuberculous forms, pulmonary, osseous, articular and intestinal. The ampoules supplied are for hypodermic use in 1, 2 and 5 cubic centimetres.

Another preparation of the same firm is *Ca Wassermann* which is a recalcifying agent, having a strong allaying action in hypervagotonia; its composition is as follows:—

Calcium gluconate	4 per cent.
Calcium pyruvic	4 " "
Calcium lactate	4 " "

It is advocated in the treatment of tuberculosis, pneumothorax, rickets, osteomalacia, fractures of bones, serious hæmorrhages and kindred ills. It is supplied in 2-, 5- and 10-cubic-centimetre ampoules for intravenous or intramuscular use, and can also be had in granule form. Messrs. Ezra Brothers, Rustom Buildings, Churchgate Street, Fort, Bombay, are the distributors in India.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

OBSERVATIONS ON AN UNUSUAL CASE OF ACUTE HÆMORRHAGIC PURPURA

By E. S. PHIPSON, D.S.O., M.D., M.R.C.P.
LIEUTENANT-COLONEL, I.M.S.

Medical Officer in Charge, European General Hospital,
Aden

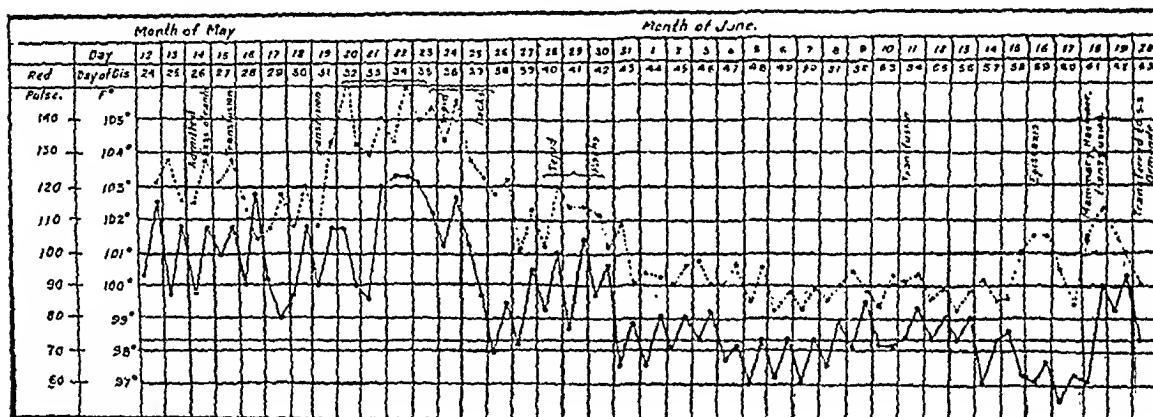

THE purpuras form a peculiar disease-group, the ultimate nature of which is very obscure. As a symptomatic manifestation purpura is associated with a wide range of diseases, many of which are completely dissimilar in character, such, for example, as syringo-myelia, chronic nephritis and smallpox, which have no single feature in common except their occasional association with capillary permeability.

In its primary or idiopathic manifestation, purpura is even more mysterious; its ætiology

disembarked from the s.s. *Otranto* on 14th May, 1933, and admitted to the European General Hospital, Aden, suffering from acute hæmorrhagic purpura.

Previous history.—The patient was an only child, and had lived all her life in the Catanian province of Sicily, in a village remote from the larger towns. Her previous health had been perfect and there was no hæmophilic or similar taint in the family. Menstruation began at the age of eleven, which is quite usual in Sicily, and it proceeded normally. Temperamentally she was very excitable and impulsive, very quick to anger, and ready to quarrel and even fight on a slender pretext. At other times, when nothing occurred to irritate her, she was of a bright and happy disposition. Before leaving Italy she had had a love affair, probably not of a serious character, but unknown to her mother. Her previous history, in so far as it indicates any abnormality, suggests, if not an actually neurotic disposition, at least a temperament less subject than usual to normal inhibitions.

History of present illness.—The patient had completed a normal menstrual period on 15th April, 1933. A few days later she was the horrified witness of a serious motor accident, which gave her a severe nervous shock, and she at once began to menstruate again, and developed what, from her mother's description, was evidently a petechial rash and numerous ecchymoses on

is, it would seem, completely unknown, its essential pathology has so far eluded attempts at elucidation, and its treatment is necessarily to a great extent empirical or symptomatic. Of the primary purpuras, the most remarkable is the acute hemorrhagic type and there are few diseases more striking in character and more dramatic in their developments, and few, fortunately, in which the physician can so safely rely on the *vis medicatrix naturæ*. Of this the most convincing proof is that, despite the absence of any agreed therapeutic rationale, the case-mortality, in any considerable series, is by no means high, and complete eventual recovery is the rule.

The following case is recorded in more detail than usual as it illustrates some of the rarer features of this remarkable disease and emphasizes one point on which all authorities are in agreement: the possibility of recovery in an apparently desperate case:

DESCRIPTION OF THE CASE

The patient, a Sicilian girl of the emigrant class, travelling with her mother from Italy to Australia, was

the limbs and trunk, and later some degree of epistaxis. She consulted a doctor locally who advised certain injections, but, in the preoccupation of the impending voyage to Australia, his advice appears to have been neglected.

The mother and daughter embarked at Naples on the s.s. *Otranto* on 6th May.

For the first four days of the voyage, the epistaxis was troublesome, but she did not seek medical advice until 10th May, when she came under the care of the ship's surgeon, Dr. B. Muir, and, in particular, of his junior colleague, Dr. R. G. Champion de Crespigny, to whom I am indebted for the notes of the case whilst the patient was on board. On 11th May, the epistaxis was severe and was followed by very extensive hæmatemesis (possibly due to swallowed blood). The condition was met by plugging the nares, the injection of horse-serum in the form of antistreptococcic serum, and by subcutaneous salines, with morphia as required. At about this time vaginal bleeding reappeared, and the patient complained of abdominal pain and headache. The temperature varied between 100° and 102°F., and the pulse was fairly steady at about 120. For the next three days her condition gradually deteriorated, and on the ship's arrival at Aden, I was consulted with a view to her disembarkation for further treatment on shore, and she was admitted to the European General Hospital on 14th May.

Condition on admission.—The patient was a girl of medium stature, robust build, and full sexual

development. Her age appeared to be seventeen or eighteen, but her actual age was fourteen. Her breasts were enlarged and full, so much so, that at first sight they suggested lactation, but although the areolæ were enlarged and tumid, the nipples were retracted and inconspicuous. The significance of this became apparent later. Her skin had to a marked degree the waxy pallor of severe secondary anæmia and there was a fine petechial rash sparsely distributed on the skin of the neck and trunk. There were fairly numerous ecchymoses on the limbs and buttocks and below each breast, perhaps a dozen in all, each about two or three inches in diameter, rather faint in colour, and apparently deep-seated in origin. Epistaxis and vaginal bleeding were in evidence and there was a well-marked internal strabismus, alternating in type, but it is doubtful whether the last-named was of recent origin.

Progress of the case.—The symptoms observed on board ship continued to increase in severity. She was given an immediate injection of 30 c.cm. of horse-serum, and six-hourly injections of 4 c.cm. of hæmoplastin (P. D. & Co.) were ordered and arrangements initiated for blood-transfusion.*

Her diet consisted of iced citrated milk and glucose lemonade and 10 per cent glucose in saline per rectum. The following day, 100 c.cm. of citrated blood was transfused, resulting in an immediate and encouraging improvement in the patient's condition; but this, unfortunately, was short-lived and the state of the patient rapidly went from bad to worse. Four days later another transfusion of the same amount was given but it seemed powerless to effect the course of the disease, and by 20th May the condition of the patient was desperate, and she appeared to be moribund.

For the next four days, the girl's condition was pitiable indeed; she lay in a state of extreme bodily weakness, her voice sunk to a whisper, her features pinched and drawn, and with the dusky circum-oral shadow which so often heralds approaching dissolution; almost blind from multiple hæmorrhages in the retinae of both eyes, uncontrollable bleeding proceeding from the nasopharynx, and continual oozing from the gums, mucous membrane of the mouth, palate and tongue; there were frequent hæmatemeses, and rectal incontinence with the continual passage of melæna with occasional gushes of altered blood in quantities which seemed inconsistent with the possibility of survival; continual bleeding in varying amount from the vagina, probably of uterine origin, and enlargement and tumidity of the labia minora, apparently due to the effusion of blood within their substance. The pulse was either hardly perceptible, or of a feeble running quality, almost uncountable, in the neighbourhood of 140 or 150. The temperature varied between 101° and 103°F. with a skin somewhat dry and harsh. The urine contained a trace of albumin but there was no indication of bleeding in any part of the urinary tract.

At this point, when the morbid processes were at their height and survival seemed hardly possible, an observation was made which gave an indication for treatment. This was that the patient was suffering from a profound degree of ketosis, the urine giving the immediate deep purple colour-reaction with Rothera's nitro-prusside test; this is rarely met with except in severe cases of

toxæmia of pregnancy and in acute yellow atrophy of the liver. The patient was promptly put on alkaline carbonates by the mouth in large doses, which fortunately she was able to retain fairly well.

About the same time an effort was made to improve the cardiac condition, although the temperature was not very high, by the old-fashioned method of tepid packs, frequently repeated. The effect on the patient's general condition from these two lines of treatment, particularly the latter, exceeded all expectations and within twenty-four hours all the symptoms showed a perceptible improvement. The pulse became slower and steadier, the pyrexia began to abate and never again attained the same height; the bleeding appeared to be less, and the patient's mental condition was noticeably brighter. It was evidently the turning point in the illness, and thenceforward the patient began an uninterrupted progress towards recovery from the attack. The bleeding gradually stopped and all other symptoms cleared up one by one; and the ketosis diminished and finally disappeared after some days.

The phase of recovery.—From the 24th May onwards, the patient's condition steadily improved, as will be seen from the chart. She was put on hæmatinics in the form of cacodylates of iron and strychnine hypodermically, and liquid liver-extract and colloidal iron by the mouth. Her appetite and digestive power soon returned. By 11th June, her appetite was voracious, and it was difficult to keep her food-intake within reasonable limits. The skin lost its waxy pallor, the features filled out again, and the lips and mucous membranes regained a portion of their normal colour. Visual acuity, which at the height of the attack was almost nil, was partially regained, up to six-eighths.

But in one respect the patient made no progress whatever. Her blood-pressure remained consistently low with a systolic pressure in the neighbourhood of 90 mm. of Hg. and the diastolic pressure of about 45 mm. The result was that any attempt to raise her from the recumbent posture, although keenly desired by the patient herself, led to the development of syncopal symptoms and had to be abandoned. A third blood transfusion was then carried out, but although it improved the general condition somewhat, it had no effect whatever on the blood-pressure. It appeared as if there was a suprarenal deficiency, possibly due to cortical hæmorrhages in the gland-substance, similar to those recorded in the fatal purpura of young infants. On this supposition, an attempt was made to remedy the defect by the cautious administration of adrenalin. This to some extent produced the desired effect. The blood-pressure could be maintained at about 110 mm. (the systolic normal for European girls of a similar age being, as ascertained from a number of observations, 115 mm. during the hot weather in Aden), but the adrenalin injections were painful and had to be abandoned. An affect was then made to bring about a similar rise in blood-pressure by the oral administration of ephedrine hydrochloride, but with indifferent success. In view of the very trying climatic conditions at that time of the year in Aden, it was then decided that no further improvement was likely to be effected in the patient's condition as long as she remained in Aden, and that she was to be sent back as soon as possible to her home in Sicily. This decision was welcomed with delight by the patient and her excitement at the prospect of the voyage home after five weeks' incarceration in hospital may have had some bearing on what followed.

Three days before she was due to leave Aden on the homeward voyage, she developed a slight return of hæmorrhagic symptoms. There was a slight oozing from the gums, with petechial maculæ inside the mouth and lips. This was followed by a slight epistaxis. This development did not occasion any particular anxiety as slight relapses are frequent in cases of purpura, but as a measure of precaution, an injection of hæmostatic serum was ordered and the fourth transfusion decided

*The supply of blood from civilian sources proved to be a difficulty. There was no lack of volunteers, but unfortunately there were no grouping sera in Aden at the time. The difficulty was finally resolved through the admirable medical organization of the Royal Air Force, by which the blood-grouping of certain airmen in each command is known and recorded, and through the good offices of my colleagues, Wing-Commander F. N. B. Smartt, R.A.F.M.S., Principal Medical Officer of the Aden Command, and, in particular, Squadron-Leader J. K. R. Landells, F.R.C.S. (Edin.), R.A.F.M.S., who produced a willing 'universal donor' and carried out the transfusions for me on four occasions. To both these officers I tender my grateful acknowledgments.

on. The following day the oozing and epistaxis had stopped.

During the process of recovery, the girl's breasts had become very much smaller and had assumed what one would judge to be the size and contour normal for a well-developed girl. On the 18th June, at about 10 A.M. the left breast began to swell rapidly, so rapidly that the moment-to-moment increase in size was almost perceptible to the eye. This continued for two or three hours, when the swelling appeared to reach its maximum. The expansion of the breast took place apparently painlessly, but the patient was not unnaturally frightened at the strange experience. At about 4 P.M. of the same afternoon the right breast began to swell in exactly the same manner, and by 7 P.M. both breasts were equally and symmetrically enlarged to the same massive dimensions, suggestive of lactation, as had been observed on her admission to hospital five weeks previously, and with much the same peculiarity of contour, namely, the enlarged and tumid areola and the retracted and almost imperceptible nipple. The cause of this swelling was, no doubt, hæmorrhage into the peri-glandular tissues of the breast and not into the gland itself. This would explain the tumidity of the areolæ and the retraction of the nipple. It seems therefore highly probable that one of the symptoms of the disease, which occurred either in Sicily or on board ship after leaving Naples, was the gradual and painless hæmorrhage into the areolar tissues of both breasts which passed unnoticed by the patient, or, if noticed, was attributed to natural development. The clue to the cause of the original enlargement was the ecchymoses under each breast observed on admission, but its significance was overlooked at the time, and the cause of their reduction in size was, no doubt, the gradual absorption of the extravasated blood during the period of recovery.

I have recorded this incident in detail, as symmetrical massive hæmorrhage into the breasts is unique in my experience in this or in any other disease. I did not regard this development as being of very serious import, as the patient's condition was otherwise quite satisfactory and the urine showed no sign of ketosis.

The following day the breasts had already begun to diminish in size and on the 20th June, after full consultation with the ship's surgeon, she was embarked as a patient on the *s.s. Ormonde* homeward bound for Naples, in the hope that she would reach Italy without further complications, and that she would have a fair chance of complete recovery in the more salubrious climate of her native Sicily.

Discussion

Very little appears to be known regarding the ætiology of this strange affliction. The most recent view, put forward by Jones and Tocantins (1933), is that purpura hæmorrhagica is a disease of the deficiency type, on the ground that blood-transfusion is the most generally effective line of treatment. These authors comment on its marked seasonal tendency—the highest incidence is said to be in the spring—and state that the disease occurs in persons of 'hæmorrhagic constitution'. The acute phase is precipitated by toxins originating from an acute or chronic infectious process which is active, or by substances which affect capillary permeability. They also believe that many cases occur in persons whose diet is ill-balanced. Examining the case under discussion in the light of these views, there appears to be no evidence of the operation of any of the antecedent conditions referred to with the

exception of the one fact that the attack began in the spring.

It is, on the other hand, possible to discern three separate factors in the present case which, acting singly or together, may stand in ætiological relationship to the actual attack. The first and most obvious is the reaction of a young girl of an excitable and unbalanced type to the severe nervous shock occasioned by witnessing a motor accident. The immediate resumption of the menstrual flow on that occasion, and the rapid subsequent development of the petechial rash and of the ecchymoses may, of course, have been purely fortuitous, but the chances are strongly against such a coincidence. The second factor is the probability of the existence of some profound metabolic disturbance, as evidenced by the very high concentration of ketone bodies in the urine at the height of the attack. The third factor is the possibility of endocrine disharmony. This may have resulted from over-action of the endocrine glands subserving the sexual function. That some such factor may have been at work is suggested by the very complete—one might say precocious—sexual development of the girl, the apparent partial failure of adrenal gland-function after the attack, and the unusually heavy involvement of sex organs in the hæmorrhagic manifestations—that is, the breasts, uterus and vulva.

As regards response to treatment, it must be admitted that the effect of the blood transfusions was disappointing. Except on the first occasion, transfusions had very little apparent effect either on the condition of the patient or on the course of the malady. This was perhaps because they were given with insufficient frequency, but with a single donor it is obvious that there are limits to his complaisance as well as to his capacity. The hæmostatic serum, of which relatively large quantities were given, appeared to have a very limited effect, if any, on the occurrence of hæmorrhage, but a marked effect on the blood after it had left the vessels. The naso-pharyngeal space after epistaxis, for example, was frequently occupied by a thrombus in the form of a cast of quite remarkable firmness and tenacity, which, until it was removed (a by no means easy manoeuvre) caused acute discomfort to the patient. So-called specific treatment, therefore, was not strikingly successful.

With regard to general treatment, there is good reason to believe that the adoption of tepid packing at the critical stage in the attack may have had a decisive effect on the circulatory system which enabled the patient to weather the storm, and I think it unlikely that the patient would have survived if the ketosis, in so profound a degree, had remained undetected and untreated.

However this may be, there is one point on which there can be no room for doubt: that the skilled nursing which the case demanded

and received was the predominant factor in the issue of the case, no doubt by fostering those inherent powers of resistance and of somatic response which together constitute the *vis medicatrix naturæ* of the old-time physicians.

It remains for me to record my indebtedness to my Resident Medical Officer, Assistant-Surgeon E. A. Eates, I.M.D., and to my matron Miss-J. Coulter, and the nursing staff, for their loyal co-operation in a difficult case, made no less difficult by the inability of the patient to speak or understand any language but Italian.

In conclusion I should like to add that the heavy cost of specific treatment in this case was met from a fund generously placed at my disposal recently by my friend Sir Prabhashankar Pattani, K.C.I.E., of Bhavnagar.

SOME OBSERVATIONS ON TWO CASES OF DISORDER OF THE LIVER IN INFANCY AND CHILDHOOD*

By S. P. BHATTACHARYA, M.D.

Officiating Professor of Tropical Medicine,
Calcutta School of Tropical Medicine
and

K. C. CHAUDHURI, M.B.

Physician-in-Charge, Children's Department,
Chittaranjan Seva Sadan, Calcutta

THE frequency of cirrhosis of the liver in infancy and childhood in India has been long recognized, but cases of disorder of the liver following a course simulating that of acute necrosis have not been reported very often in this country. Furthermore, the subject of cirrhosis has by no means been exhaustively studied, and a satisfactory explanation of many a feature of this illness is lacking.

Recently we came across two cases—one of acute necrosis in a child aged seven and a half years and the other of cirrhosis of the liver in an infant aged one year—in the Carmichael Hospital for Tropical Diseases. Certain observations were made on these cases, which are the subject-matter of this communication.

Case 1.—N. R. B., a boy, aged 7½ years, was born of healthy parents at full time. He was a resident of Rampurhat in Bengal. There was no history of any previous serious illness, neither was there any history of drug or alcohol administration. He took the usual Bengali diet consisting of rice, vegetables, fish, eggs and milk. His parents, brothers and sisters are healthy. No member of the family has had any disorder of the liver, neither was there any history of syphilis.

He had frequent, watery motions on the 10th December, 1932; this condition continued for about 10 days, and is reported to have been relieved by the administration of castor-oil emulsion. But he caught a chill and had a swelling of the right auricular region soon after. Following this he had a slow rise of temperature, enlargement of the liver, and jaundice. His condition

improved considerably on a restricted diet containing very little fat, and on receiving three injections of emetine hydrochloride, grains 1/3 each, and a mixture containing salicylates. He was put back on to normal diet as he had no symptoms for about a week. On 5th January, 1933, his condition became suddenly very much worse, as evidenced by the appearance of deep jaundice, swelling of the legs, and rapidly-developing ascites. He was admitted to the hospital in this condition on the 24th January, 1933.

On admission to the hospital the patient was found to be a well-developed boy for his age. There was deep jaundice of the skin and sclera, and œdema of the lower extremities and eyelids. He looked markedly anæmic. The abdomen was protuberant with a considerable amount of ascites. The liver was palpable, hard and smooth, but not tender. The spleen was not palpable. The tongue was clean and moist. There was neither caries of the teeth, nor pyorrhœa alveolaris. The tonsils were septic. The apex of the heart was in the fifth intercostal space at the left mammary line and the precordial dullness extended to this line on the left. There was a thrill and a presystolic murmur at the apex. There was no evidence of disease of respiratory, nervous, or any other system.

Figure 1

Case No. 1.....N.R.B.....Age 7½ years.

Temperature ——— Pulse ——— Respiration ———

* Being a paper read at the British Medical Association (Calcutta branch) on the 21st April, 1933.

Investigations.—Van den Bergh's test gave both 'direct' and 'indirect' positive reactions. Blood examination on the 26th January revealed 45 per cent hæmoglobin, 3,070,000 erythrocytes, and 7,800 leucocytes per cubic millimetre, of which 88 per cent were polymorpho-nuclears, and 12 per cent lymphocytes. Fasting blood-sugar was estimated to be 0.065 milligramme per cent. The Wassermann reaction was negative and the blood was also negative for filaria. Microscopical examination of the stool showed no parasites or ova. Culture of the stool showed *B. pseudo-carolinus*. An examination of the urine done outside on the 16th January showed a trace of sugar. After the administration of 10 grammes of lævulose and 15 grammes of glucose the urine showed lævulose and bile pigment in fair quantities but no glucose; there was a trace of albumin but no casts.

The patient was given no lævulose and was put on a diet consisting of two pints of milk, four ounces of sugar, two ounces of butter, one egg, two oranges and eight ounces of bread daily. Urine examination showed the reaction acid, no glucose, leucin or tyrosin, and no leptospira. The other findings are shown in table I below. For the temperature, pulse rate, respiration and urine reports *vide* figure 1.

TABLE I

Date	Albumin	Lævulose	Bile-pigment	Casts
24-1-33	Nil	++	Nil	Nil
26-1-33	Nil	Nil	Nil	Nil
1-2-33	Trace	++	++	Nil
2-2-33	Trace	+	++	Hyaline granular Do.
4-2-33	..	Nil	++	

Lævulose was tested by polarimeter.

The lævulose-tolerance test was done to determine the efficiency of the liver; the results are tabulated in table II and in figure 1, compared with a control case.

TABLE II (*vide* FIGURE 2)

(Ten grammes of lævulose by mouth)

	Blood sugar, milligramme per cent.
Fasting	0.065
After 45 minutes	0.080
After 90 minutes	0.090
After 135 minutes	0.095

The blood sugar was estimated by the calorimetric method by Dr. J. P. Bose.

Progress.—The condition of the patient remained steady during the first few days. His appetite improved slightly on being given hypodermic injections of 5 units of insulin coupled with 4 drachms of glucose by mouth, but he did not improve very much. He was then given a fat-free diet consisting of 16 ounces of skimmed milk, 4 ounces of sugar, 3 oranges, one and a half pints of coconut water. The total output of urine diminished very much and on 1st and 3rd of February he was given two intramuscular injections of 0.25 and 0.50 cubic centimetre of novasurol, which increased the output from 6 ounces to as much as 28 ounces in a day, as will be seen from figure 2. His condition gradually became worse and on the 4th February he developed symptoms of loss of vision and hearing, and then passed on to a semi-conscious state. He died on the 6th February. No autopsy was permitted.

Comment

The clinical character of this case resembles very much those described by Wallgren (1930),

Figure 2.

Case No. 1.....N.R.B.....Age 7½ years.

Bergstrand (1930), Williams (1923), Roman (1927) and Morgan and Brown (1927), in which the onset was like that of a benign catarrhal jaundice, then there was slight temporary improvement, followed by the sudden appearance of symptoms pointing to an acute insufficiency of the liver. These authors attempted to establish the relationship between epidemic catarrhal jaundice and toxic necrosis. Many chemicals, such as organic arsenicals, trinitoluene, phosphorus and chineophen, which are known to produce acute necrosis, could be excluded in this case. Both epidemic and sporadic forms of Weil's disease being scattered throughout the country, leptospira infection should be considered as a possible ætiological factor. But the clinical history and course of the disease, and also the absence of leptospira in the centrifugalized deposit of the urine of the patient from the 10th day onwards, provide strong presumptive evidence against its being due to leptospira icterohæmorrhagiæ, although the negative findings might be of questionable value in some instances. Congenital syphilis, typhoid and para-typhoid fever, malaria, tuberculosis, scarlet fever, diphtheria and pertussis can easily be excluded on the basis both of clinical and laboratory findings.

Bergstrand (1930), and Findlay, Dunlop and Brown (1931) have expressed the view that epidemic catarrhal jaundice is probably due to a virus infection, which though pathogenic for man cannot be inoculated into experimental animals. It is possible that acute necrosis of the liver is due to super-added toxæmia in a patient whose liver has been previously damaged by such virus and has not recovered fully after a primary attack. Opie (1910) found acute hepatic necrosis from a combined action of chloroform and *B. coli*. Hurst and Hurst (1928)

produced more marked changes by combining the action of manganese chloride and *B. coli*. Findlay *et al.* (1931) showed that the extent of necrosis is far greater with combined arsaphamin and *B. coli* than with either of them alone. One of us (S. P. B.) observed in a fair number of cases of infantile cirrhosis of the liver, secondary infections with streptococci, *B. coli*, *B. faecalis*, etc., and isolated them from the puncture fluid of the liver and in some instances confirmed these findings by post-mortem examination. Moon (1932) has conclusively demonstrated streptococci in histological specimens of the liver and Bergstrand recovered *Streptococcus viridans* in pure form from the duodenum. Maedonald (1918) reported secondary infection with streptococci in acute necrosis of the liver.

was not recent and was probably connected with the throat infection. The rhythm was regular—90 per minute. There was no extrasystole. The deep jaundice, the irregular rise of temperature, and œdema of the whole body could not be attributed to a cardiac lesion.

A marked disturbance of the functions of the liver is demonstrated by the results of the lævulose-tolerance test. It has been universally accepted that in healthy subjects the blood-sugar level shows hardly any variation after the administration of lævulose, but in disorders of the liver alimentary hyperglycæmia is noticed. It will be seen that in this case the blood-sugar level has increased 35 milligrammes per cent over the initial value which is far from normal. Poynton and Wylie (1926) noted blood-sugar

Fig 3.
Case No. 2. G. I. Age... 1 yr.

Temperature — Pulse - - - - - Respiration o - - - - o Body weight o + + + o

In this case streptococcal infection on the top of a catarrhal jaundice is a reasonable possibility, although a definite proof is difficult to get. There was no jugular pulsation in the neck and the boy suffered no distress whilst lying on his back. There was an enlarged heart with a valvular lesion, but there was no tenderness of the tip of the fingers or toes, no sign of embolism, spleen neither enlarged nor tender, no arteritis of peripheral vessels, no finger clubbing, and no petechiæ noticed. The cardiac lesion

value, which is 'slightly below the average, being 0.053 and 0.056 respectively' in their cases. The initial blood-sugar value in our case, namely 0.065, is definitely below the average in this country. Mann (1927) reported in a recent paper that the complete or even incomplete extirpation of the liver in experimental dogs produces loss of sight and hearing, and coma with concomitant development of hypoglycæmia, ending in death. This could be avoided by repeated administration of sugar.

In our case the symptoms of hypoglycæmia and insulin shock were prevented for a time by the repeated administration of glucose, but after a certain length of time the patient developed loss of sight and hearing, and coma supervened ending in death. This might be due to the sudden disability of a large portion of the liver resembling a partial extirpation, as in experimental animals, because the train of symptoms simulated very much those produced in experimental animals.

In our case the almost constant presence of lævulose in the urine except just before death is remarkable. Then sugar that was reported to be present in the urine on the 16th January was perhaps lævulose, as it was not polarimetrically examined at the time. Lævulose was excreted in the urine both on a mixed diet and on administration of lævulose by mouth, and therefore it could not be considered that it was only a diminished lævulose tolerance, as is seen in functional disorders of the liver, but lævulose diabetes, because lævulose was present even on starvation or when a mixed diet was given. Warkany (1927) reported such an instance of essential lævulosuria in a child suffering from cirrhosis of the liver of tuberculous origin. Barrenschen (1922) also reported a case and collected eleven others from the literature.

It is thus seen that the carbohydrate metabolism is markedly disturbed in this instance. Associated with lævulosuria there is definite hypoglycæmia, which can be reasonably compared with the glycaemic reaction of the diabetic. On oral administration of lævulose, there is a rise of blood-sugar level, which is not seen in normal subjects. This disturbance is undoubtedly due to changes in the liver and perhaps can be explained only on the following assumptions :—

1. Inability of the liver to convert lævulose into dextrose or glycogen.
2. Inability to store glycogen.

The positive van den Bergh reactions, both 'direct' and 'indirect', which suggest obstruction of the bile passages with fair degree of liver damage, and the clinical signs, namely, jaundice, ascites, enlarged liver, etc., all point to gross disorder of the liver, and lævulosuria is another manifestation of this disorder. That the liver was poor in glycogen store is obvious, because the blood-sugar level on fasting was very low.

Case 2.—G. I., a boy, aged 12 months, was born of healthy parents at full time. His parents used to live in Madras and came to Calcutta only in November 1932. Both the parents are healthy and the mother has had no miscarriages. There is no history of syphilis, or alcohol. The health of the other children is good. The child had been fed with diluted cow's milk and butter-milk since a few days after birth, and was seldom breast-fed. The only previous illness that he had had was slight fever and cough, and occasional diarrhoea. On the 2nd January, 1933, he had a little cough and, on the 6th, fever. Three days later he is reported to have passed greyish stools and on the 12th February he developed jaundice, which gradually

deepened. On the 16th January he was admitted to the hospital with deep jaundice, ascites and in a very low condition. For the temperature, pulse rate, respiration and body weight *vide* figure 3.

On admission to the hospital the patient was found to be deeply jaundiced and emaciated. He presented an anxious, irritable and anæmic appearance. Muscles and subcutaneous fat were very much reduced and turgor was severe. The skin and conjunctivæ were tinged deep yellow. Veins were dilated and prominent on the chest and abdomen, and showed centripetal distribution. The fontanelle was open and two finger-breadths in width. The child had not cut any teeth. He could not sit, stand, nor speak. His body-weight was 12.8 pounds and height 27 inches. The abdomen was protuberant, its girth being 17.75 inches, with ascites. The liver was enlarged two finger-breadths below the costal margin. It was hard, uniformly smooth and not tender. The spleen was just palpable. The thorax was symmetrical and moved equally on both sides with respiration. Signs of bronchitis were present in both the lungs. There was no evidence of disease of the nervous or any other system.

Investigations.—Van den Bergh's test was strongly positive both for 'direct' and 'indirect' reactions. On examining the blood on the 17th January the erythrocytes amounted to 3,150,000 and leucocytes 36,900 per cubic millimetre of which 83 per cent were polymorphonuclears, 14 per cent lymphocytes, 1 per cent mononuclears and 2 per cent eosinophiles. Hæmoglobin was 50 per cent. The Wassermann reaction was negative. Microscopical examination of the stool revealed nothing except the ova of trichuris and culture of the stool showed *B. pseudo-carolinus*. The fat-content of the stool was found to be 2.26 per cent total fat, of which 1.06 per cent was saponified fat, 1.16 per cent non-saponified fat, 0.62 per cent fatty acid and 0.44 per cent neutral fat. Urine examination showed nothing, but lævulose appeared on the administration of 10 grammes of lævulose by the mouth. On culturing a catheter specimen, *B. pseudo-carolinus*, non-lactose

Figure 4
Case No. 2.....G.I.Age 1 year.

fermenters and some fine colonies of streptococci were notified. The results of the lævulose-tolerance test are given in table III.

Röntgenological examination of the skeletal bones showed no rickets or syphilitic change (*vide* skiagram).

TABLE III (*vide* FIGURE 4)
(Ten grammes of lævulose by mouth)

	Blood sugar, milligramme per cent.
Fasting ..	0.149
After 45 minutes	0.190
After 90 minutes	0.280
After 135 minutes	0.220

Progress.—His condition improved transiently on administration of three drachms of glucose by the mouth, and giving 3 to 7 units of insulin hypodermically daily. About a week after admission he developed constipation and troublesome tympanitis, and died on the 1st February, *i.e.*, within 4 weeks of the onset of the first symptom. The course of the disease is represented graphically in figure 3 and a picture of the patient is seen in figure 5. No autopsy was permitted.

changes of rickets. In figure 6, if the skiagram of the wrist of this case is compared with that of a case of rickets, the difference will be obvious to all. In contra-distinction to the view of Naegeli and his collaborators (1931) who observed leucopenia and characteristic granules in the mononuclears, and also to the Mexican series of cases where leucopenia was observed, we have found leucocytosis in this case as well as in many other similar cases. The course of the disease in this instance was unusually rapid and this is perhaps due to the fact that the patient was debilitated and had been artificially fed from the very beginning. On the basis of clinical and laboratory findings, it is impossible to distinguish this case imported from South India from those seen locally. Strongly positive 'direct' and 'indirect' van den Bergh reactions suggest that there was both obstruction of the bile passages and destruction of the

Figure 5

Comment

The diagnosis of this case did not offer much difficulty as almost all the classical signs and symptoms of cirrhosis of the liver, namely, ascites, dilatation of the abdominal veins, jaundice, enlargement of the liver and clay-coloured stools, were present. Poynton and Wyllie (1926) mention that special features related to cirrhosis of the liver in childhood are infantilism, familial incidence and hæmorrhages. Although the familial occurrence and hæmorrhages have not been noticed in this case the signs of infantilism were distinct and unmistakable. Small stature, delayed dentition, open fontanelle, and inability to sit, stand or speak, might be considered as of rickety origin but röntgenological examination of the skeletal bones revealed none of the characteristic

liver cells. There was also definite sign of hepatic inefficiency, as shown by the lævulose-tolerance test. As will be seen from the figure there was very marked deviation of the blood-sugar level, after the administration of 10 grammes lævulose. The rise amounted to as much as 131 milligrammes per cent over the initial blood-sugar level as compared to the rise in normal cases. Hyperglycæmia is also a notable feature which is seen in this case as well as in others of a similar nature.

The search for an explanation of the cirrhosis has given rise to much speculation. Known causes of this disease, syphilis, the alcohol habit, tuberculosis, malaria, kala-azar, congenital malformations of the hepatic system, and acute infections, the rôle of which has been particularly stressed by Osler (1903), could be

definitely excluded. A parasitic type of cirrhosis is known, in which various forms of schistosome are concerned. No parasites or ova were discovered in this case. In many such cases where the origin remains obscure, a

Figure 6
Skiagram

toxin of chemical, metabolic or bacterial origin is perhaps at work. Rolleston (1912) suggested 'a local result of a chronic general toxæmia, with the conveyance of the toxin to the smaller bile ducts by means of the hepatic artery'. Theories differ as to the character of the poison. It is likely that a toxic substance is produced under certain circumstances, which might act as a provocative agent. deRaadt (1930) thought that conditions, which greatly and for a long period increase the conversion of intestinal ammonia into urea by the liver, result in cirrhosis. A diet containing a small amount of nitrogen, such as strictly vegetable diet, would then act in this way. Many difficulties beset the determination of the exact ætiology of the cirrhosis of the liver. At the present stage of our knowledge it is impossible to state anything definite about the nature, origin and pathogenesis of these cases. It must be left to the future for discussion and determination.

STUDIES ON THE ACTION OF ATEBRIN IN PLASMODIUM INFECTION OF MONKEYS

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pharmacology

and

B. M. DAS GUPTA, L.M.P.

Officiating Professor of Protozoology

(From the Departments of Pharmacology and Protozoology, School of Tropical Medicine, Calcutta)

NAPIER and Campbell (1932) found that the blood of a monkey imported from the Malay States—*Macaca irus*—contained a protozoal parasite in the red blood corpuscles resembling the malarial parasite. This monkey did not seem to be in any way affected by this infection, which was never intense and which was not always patent, even when a careful and prolonged examination of the blood was made. A few cubic centimetres of the blood of this monkey, in citrated saline injected intravenously into a *Macaca mulatta*, the common monkey occurring in Bengal and many parts of India, transferred the infection to the latter animal.

The course of the infection was intense and if allowed to progress, as many as 60 per cent of the red blood cells became infected, and the animal rapidly succumbed.

Knowles and Das Gupta (1932) carried out exhaustive studies in connection with this infection and confirmed the findings of Napier and Campbell. They showed that this parasite occurs as a natural infection in *M. irus*. In this host the infection is scanty, and either spontaneous recovery occurs within a few days or weeks, or a very light infection persists off and on for periods up to seven months or more. No symptoms are produced and morphologically the parasite resembles *P. vivax* of man, and gametocytes are relatively abundant.

Macaca mulatta however is exceedingly susceptible, and the infection invariably proves fatal, usually within a week or less of the first appearance of the parasites. This animal can be infected with an extremely minute dose, e.g., a total inoculation of 16,000 parasites given intravenously or subcutaneously. The fever rises to 106.2°F. (normal temperature being 102° to 103°F.), the animal becomes ill and suffers from profound and progressive anaemia. All phases of the schizogony cycle are seen in the peripheral circulation whilst the terminal phases of infection are of terrific intensity with a parasite count of 3½ million per cubic millimetre. The internal viscera are crammed with parasites and the terminal infection is sometimes accompanied by hæmoglobinuria. Death occurs after a sudden fall of temperature to subnormal.

The infection can also be communicated to some of the other monkeys commonly occurring in India:—(1) in *Macaca radiata*, the parasites are scanty, persist from 5 to 40 days, the count is very low, and spontaneous recovery usually occurs. (2) *Semnopithecus entellus*—the common 'hanuman' monkey of India—is nearly as susceptible as *M. mulatta*; severe infection occurs and progressive anaemia develops leading to a fatal termination. (3) *Hylobates hoolock*—the 'hoolock anthropoid' of Assam—is only slightly susceptible and shows transient infection for a few days unaccompanied by any symptoms.

It has been found that *M. mulatta* and *S. entellus* when infected with this parasite readily react to treatment with anti-malarial drugs, provided of course that the infection has not proceeded beyond a certain limit. Napier and Campbell in their early experiments found that, by giving the infected animal one grain of quinine by the mouth for about a week and then a single dose of 1 to 2 grains every now and then, the infection could be kept in check. Chopra, Mukherji and Campbell (1933) tested the action of some cotarnine derivatives supposed to have anti-malarial properties on *M. mulatta* infected with malaria and obtained results corresponding to those obtained in human beings. Knowles and Das Gupta have shown

that in this species the earlier ring and trophozoite phases bear some morphological resemblance to *P. falciparum* of man, whereas the gametocytes resemble those of *P. malaria*. These workers were successful in transferring this infection from *M. mulatta* to man. After inoculating the blood of infected monkeys into human volunteers they not only produced clinical symptoms such as fever, but found rings and trophozoites in the peripheral blood. Such infected blood inoculated into a *M. mulatta* carried back the infection to these animals after an incubation period of 7 days. This plasmodium, *Plasmodium knowlsi*, Sinton (1933), would thus appear to be more closely related to that occurring in man than plasmodia occurring in birds such as canaries, Java sparrows, etc., and the experimental results should therefore be more readily applicable to man.

In view of what has been said it will be seen that the two species, *M. mulatta* and *S. entellus*, infected with monkey malaria should form a very suitable medium for testing the action of anti-malarial drugs, a number of which have been synthesized lately and some of which have been put on the market. The infection in these monkeys is so intense that it will go on to fatal termination unless the drug is effective. Further, in these animals the course of infection can be watched by carrying out daily counts of the parasites and the treatment can be started at any stage desired. The control of infection by a remedy in such animals is a crucial test of its anti-malarial value as there is no chance of a spontaneous cure especially in the *M. mulatta*. The routine usually followed in this work was to test the drugs on the monkeys infected with malaria first. If beneficial results were produced trials in human patients were carried out. In this paper we give the result of our trial with atebirin.

Experimental

In the following tables are given the results of trials of atebirin in twelve monkeys. The drug was given intravenously and intramuscularly for the reason that in this way a quick and certain action is ensured. The drug given by the mouth in these animals is often kept in the pouch in the neck in which food is stored, and may later be rejected. The introduction of drugs by a stomach tube has been tried but this is liable to produce injury in the region of the pharynx and oesophagus and lead to death from sepsis and pneumonia. This method was therefore not adopted. There is ample evidence however to show that whether the drug is given by the mouth, intramuscularly or intravenously, the results are analogous. The animals under experiment were observed for prolonged periods, in some cases for many months.

The animals used in our experiments were all *Macaca mulatta* because of their ready availability, convenient size and low cost. Besides, spontaneous cure very rarely occurs in

S. entellus, and it practically never occurs in *M. mulatta*. These animals were infected by subcutaneous injection of heavily parasitized blood from *M. mulatta* previously infected. The weight of the animals used varied from 3.2 to 4.7 kilogrammes, except for one large monkey weighing over 5 kilogrammes and a young one less than 2 kilogrammes. In almost every case the treatment was commenced when the infection was very heavy, the maximum count being 1,200,000 parasites per cubic millimetre. Atebrin was given in daily doses of 0.025 gramme in most cases either by the intravenous or intramuscular route. This dose was well tolerated by monkeys of average weight, larger doses producing untoward effects; doses of 0.04 and 0.05 gramme intravenously always proved fatal in 10 to 20 minutes.

In the following tables detailed observations on these animals are summarized:—

No. I, *Macaca mulatta*, 5.3 kilogrammes in weight inoculated with 0.5 cubic centimetre of blood from an animal showing a very heavy infection (counts not done). Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
26-12-32	?	..	Rings +.
27-12-32	180,000	Atebrin 0.025 gm. i.v.
28-12-32	58,400	Do.
29-12-32	1,600	Do.
30-12-32	Scanty	..	Anisocytosis. Basophilia +.
31-12-32	0
2-1-33	0	..	Anisocytosis +. Normoblasts +.
3-1-33	0
4-1-33	0	..	Scanty pigment-bearing leucocytes.
5-1-33	0
9-1-33	?	..	Rings and schizonts.
10-1-33	508,800	Atebrin 0.025 gm. i.v.	All phases parasites.
11-1-33	440,000	..	The animal is very ill. No injection given. All phases parasites.
12-1-33	Died last night. Heart blood shows a very large number of parasites.

In this animal three doses of atebrin were given intravenously when the parasite count of the peripheral blood was very high. The parasites disappeared after the injections but reappeared 11 days later (9th January, 1933) and rapidly increased in number (10th January, 1933). An intravenous injection of 0.025 gramme was given (10th January, 1933) and next day the number of parasites decreased somewhat but the animal died. It had not been realized that relapse takes place so quickly after atebrin and therefore the drug was not administered earlier. It would however appear that once the parasites increased beyond a certain limit atebrin might not be very effective in checking their growth.

No. II, *Macaca mulatta*, 4.64 kilogrammes in weight inoculated with 0.5 cubic centimetre of blood containing 244,000,000 parasites. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
19-12-32	Scanty	..	Rings.

28-3-33	0
18-4-33	0
21-4-33	0
17-7-33	Animal died—post-mortem showed consolidation of both lungs. No parasites in the heart blood.

In this animal atebrin 0.01 gramme was given intravenously for 3 days when the parasite count was not very high. The parasites disappeared for 2 days but reappeared in increased numbers. 0.025 gramme of atebrin was given intravenously (30th December, 1932). The animal showed parasites in the peripheral blood every now and then but the infection appears to have lost its virulence. This animal has been under observation for about seven months.

No. III, *Macaca mulatta*, 2.965 kilogrammes in weight inoculated with 0.35 cubic centimetre of blood containing 168,000,000 parasites (almost all phases). Incubation period 5 days.

Date	Parasite count per c.mm.	Treatment	REMARKS

23-2-33	Monkey died. Heart blood shows very numerous parasites.

In this animal atebirin 0.025 gramme was given intramuscularly for 4 consecutive days when the parasite count in the peripheral blood was very high. The blood became free from parasites after 2 injections (8th February, 1933). The monkey suddenly died 15 days later (23rd February, 1933) and blood from the heart showed numerous parasites.

It will thus be seen that monkeys I, II and III, all relapsed after receiving 3 and 4 doses of atebirin both by the intramuscular and intravenous routes. In no. III, no treatment was given as the significance of occurrence of relapses after treatment had not been appreciated.

No. IV, *Macaca mulatta*, 3.565 kilogrammes in weight inoculated with 0.4 cubic centimetre of blood from a heavily infected animal (counts not done). Incubation period 7 days.

This animal has been under observation for five months, 0.025 gramme given intravenously for four days when the parasite count was not high. The parasites disappeared, but reappeared 12 days later (18th March, 1933). A dose of 0.025 gramme of the drug was given and after this the parasites disappeared but reappeared again. Ring forms and schizonts were both seen but the infection appeared to have lost its virulence and did not progress to a fatal termination.

No. VI, *Macaca mulatta*, 3.2 kilogrammes in weight inoculated with 0.5 cubic centimetre of blood containing 42,140,000 parasites (rings and schizonts predominating). Incubation period 7 days.

This animal has been under observation for about four months. Atebrin in doses of 0.025 gramme was given intravenously for five days when the infection was heavy. The parasites disappeared but reappeared nine days later (18th March, 1933) and a further dose of 0.025 gramme was given intramuscularly. After this the parasites disappeared but reappeared later. The infection however seems to have lost its virulence and did not progress to a fatal termination. For the last two months no parasites have been detected, and the animal is still under observation.

No. VIII, *Macaca mulatta*, 4.9 kilogrammes in weight inoculated with 0.5 cubic centimetre of blood containing 210,000,000 parasites (chiefly schizonts). Incubation period 8 days.

This animal was given 0.05 gramme of atebtrin intramuscularly for five days and the parasites disappeared from the peripheral blood. Thirteen days after the last dose the parasites reappeared and another dose of 0.05 gramme of the drug was given intramuscularly (27th June, 1933). The parasites reappeared a fortnight later (10th July, 1933) and after persisting in the peripheral blood for some time they disappeared spontaneously. The animal is still under observation.

No. X, *Macaca mulatta*, 6.1 kilogrammes in weight inoculated with 0.5 cubic centimetre of blood from a heavily parasitized monkey. Incubation period 7 days.

Date	Parasite count per c.mm.	Treatment	REMARKS
7-7-33	?	..	Rings and growing trophozoites present.

26-7-33	?	..	A few rings and schizonts.

This animal was given 0.05 gramme of atebrin intramuscularly on five days.

Nos. XI and XII died during intravenous injections of 0.05 gramme of atebrin.

Summary and discussion

The above results of these preliminary experiments regarding the action of atebrin on a small series of *M. mulatta* infected with *Plasmodium knowlsi* brings out certain interesting and important points with regard to the action of this drug. It has therefore been considered advisable to publish our findings. It is fully realized, however, that the series is too small upon which to draw any general conclusions and further work to elucidate various problems which have arisen in this connection is in progress.

Destructive action on the plasmodium.—The destructive action of atebrin on this plasmodium would appear to be exceptionally powerful. Usually two doses of 0.025 gramme each given either intramuscularly or intravenously are sufficient to control a very heavy infection which may amount to a million parasites per c.mm. The drug equally effects both the schizogony and the gametogony of this plasmodium and all phases of the parasite disappear rapidly from the peripheral circulation under its action. Even after a single dose, signs of degeneration are seen in the parasites and their numbers rapidly decrease. After two or three doses they disappear from the peripheral blood altogether.

Owing to its slow excretion atebrin, when given intravenously, appears to exert a more prolonged action than quinine on *P. knowlsi*. Our observations show that intravenous injections of quinine are not effective against a heavy infection with this plasmodium in *M. mulatta* unless they are repeated at short intervals, say of three or four hours, but one injection of atebrin suffices. It would appear that the growth of the parasites is not checked by

quinine, probably because of its rapid excretion after intravenous injection.

Dosage.—A monkey of 5 kilogrammes body weight or even smaller animals can stand a dose of 0.025 and 0.05 gramme of atebrin, intramuscularly without any untoward effects. By the intravenous route however doses larger than 0.025 gramme often produce death and we lost two monkeys in this way in the early part of our studies. As the intravenous route has no advantage with atebrin we now use intramuscular injections of 0.025 to 0.05 gramme of this drug in our experimental work. Such doses are very well tolerated and are relatively very large compared with the safe dose of 0.1 gramme thrice daily given in adult human beings of 50 to 60 kilogrammes body weight; this shows that the toxicity of the drug is low.

Relapses.—Atebrin has earned a great reputation as a powerful remedy in preventing relapses in all species of human malaria. Green (1932), treated 15 cases with 0.1 gramme of atebrin thrice daily for five days with no relapses, while there were 13 relapses among 24 controls treated with quinine. James and his colleagues (1932) treated 15 experimentally infected cases with similar doses and only one relapsed; four of them were chronic cases and had several relapses previous to treatment with atebrin. Five cases infected at Horton with the malignant 'Rome' strain of *P. falciparum* had no relapse after a course of atebrin, but two controls treated with quinine relapsed. Similar results have been recorded by Sioi, Hooper, De Uells, Jains and many others. In view of this evidence, the drug would appear to be more effective than quinine in curing malaria and preventing relapses, but so far as relapses are concerned this is not our experience with the Indian strains of malaria.

Whatever may be the case with human malaria, in monkey malaria relapses undoubtedly occur. In *M. mulatta* infected with *P. knowlsi* even after 5 days intensive treatment with large doses of the drug, the parasites invariably reappeared in 10 to 15 days and multiplied with the same rapidity as in the primary attack, causing death of the animal if prompt treatment is not given. The recrudescence can however be checked much more easily than the original attack. One dose as a rule suffices to control the multiplication of the parasites though a low grade of infection persists for a long period. A perusal of tables I to X will show that in the first relapse, if not treated, the parasites show just as great a virulence as in the primary infection, and they increase in number with great rapidity, causing death of the animal. At this stage one dose of atebrin usually suffices to stop the growth of the parasites and prevent a fatal termination. After such a dose the parasites appear to lose their virulence and either a scanty infection may persist or the parasites may disappear from the

STUDIES ON INGUINAL GRANULOMA*

II. THE BACTERIAL FLORA OF GRANULOMA

By T. BHASKARA MENON, M.D., M.R.C.P.

Pathologist to the Government Royapuram Hospital,
Madras

and

D. R. ANNAMALAI, L.M.S.S.A.

Assistant Pathologist to the Government Royapuram
Hospital, Madras

[Received for publication on 18th April, 1933.]

A DETAILED study of the bacterial flora met with in cases of inguinal granuloma was undertaken, since the question of the ætiological agent has not yet been settled. In all, eighteen cases clinically diagnosed as granuloma were studied. In each case a dark-ground examination was first made by the venereal surgeon for *Treponema pallida*, and only cases that were proved negative are included in this study. The clinical diagnosis had to be subsequently revised in three cases, one of which proved to

(Continued from previous page)

peripheral circulation for long periods without further treatment. Whether in course of time they will regain their virulence is now being studied.

Toxic symptoms.—One of the 10 monkeys passed liquid stools for two days after 4 injections of 0.05 gramme each and showed disinclination for food. There was no inflammatory cell exudate in the stools but they contained active motile *E. histolytica*, an *Enteromonas* sp and a few *Balantidium coli*. These protozoa are often found in apparently healthy animals of this species. Diarrhœa stopped spontaneously as soon as atabrin was discontinued. Two monkeys developed slight yellow coloration of the skin of the palms of the hands and conjunctivæ but this did not persist. The yellow tinge disappeared a few days after atabrin was stopped. No symptoms showing involvement of any other organ were observed.

*Rearranged by Editor.

be an epithelioma on pathological examination, while another proved to be a case of ulcus molle serpinosum in which Duerrey's bacillus was found. The third case proved to be an unusually chronic type of chancre, which subsequently gave a strongly positive Wassermann reaction and promptly responded to neosalvarsan. Our bacteriological findings in the remaining fifteen cases are given below:—

Spirochætal organisms.—*T. schaudinni* in company with *Bacillus fusiformis* was found in two cases, *T. refringens* was found six times and *T. minuta* once. We did not find *T. aboriginalis* which has been found by Cleland (1909) in granuloma.

In ten cases we found Hoffman's bacillus which is recognized as a common secondary saprophyte in lesions of the genitalia, and in two instances we found an organism resembling *B. diphtheria*. Both of these bacilli were non-pathogenic to guinea-pigs.

Staphylococci were found in twelve of the fifteen cases, but streptococci were only isolated from one case.

A Gram-negative coccus occurring singly or in staphyloid groups was found in smears in four of our cases. Pure cultures were grown from two of the cases. The colonies resembled those of streptococci at first, but they gradually became larger and more opaque reaching a diameter of about one millimetre in seventy-two hours. Microscopically they resembled staphylococci in their arrangement, but individual organisms were smaller. Injected subcutaneously into a white rat they appeared to be non-pathogenic for they produced only a slight local reaction which had disappeared in forty-eight hours.

We found *Bacillus coli* on two occasions only, but this is possibly because we got rid of surface contaminating organisms by cleaning the ulcers with saline dressings for some days before examining them bacteriologically. This also possibly explains our failure to find *B. lactis aerogenes* var. *encapsulatus* which Castellani and Mendelson (1929) consider to be frequently found in inguinal granuloma.

B. pyocyaneus was found in two cases and *B. proteus vulgaris* in one case.

Plump diplo-bacilli, Gram-negative, 2.5–3µ by 1–1.5µ in size occurring almost invariably in pairs and occasionally in short chains were occasionally met with in smears. They occurred in five of our cases. Photomicrograph I shows these organisms lying side by side with a cluster of the Donovan organisms. Growth occurred on rabbit's blood, but the organism has not been isolated in pure culture. This organism is probably identical with a diplo-bacillus that is normally found in the urethra.

Leptothrix-like filaments have been occasionally met with in culture on Norris' medium, but are infrequent. Yeasts have also been met with in smears infrequently.

B. ducreyii, the causative organism of soft sore, has been put forward by MacDonagh (1920) as the probable ætiological agent. Walker has cultivated a capsulated organism from cases of granuloma and MacDonagh suggests that this might be a capsulated variety of *B. ducreyii*. Ulcus molle serpiginosum bears some resemblance to granuloma. The chief distinction is that the process is more acute than granuloma. This view is certainly of great interest since the racial distribution of the disease, its strict limitation to particular classes and its great prevalence among abori-

Photomicrograph I.—Large plump diplo-bacilli near a cluster of extracellular Donovan bacilli (X2000).

ginal races, all suggest the possibility of a variation in type from soft sore. De Monbreun and Goodpasture (1931) have found Ducrey's bacillus in three out of six cases studied. In order to test the correctness of this view, a careful examination was made of smears from the edge of the ulcers for the chain forms of Ducrey's bacillus, which are characteristic of soft sore. These were not however found in any of our cases except the one that was proved to be soft sore subsequently. An attempt to culture the organism was therefore carried out in six of our cases, defibrinated rabbit's blood mixed with 2 per cent agar being used as the medium. The medium was prepared in the proportion of 30 per cent of rabbit's blood in agar and the tubes were inoculated on the same day. Whole blood was also used. In all cases the typical chain forms of the organism could not be demonstrated.

The Donovan organism was demonstrated in smears in fourteen of the fifteen cases studied. In one case where the smear was negative, extensive healing had occurred and there was little ulceration. The organism however was recovered in culture. Out of the thirteen cases in which cultures were carried out, the organisms

STUDIES ON INGUINAL GRANULOMA

III. THE DONOVAN ORGANISM OF GRANULOMA

By T. BHASKARA MENON, M.D., M.R.C.P.
Pathologist to the Government Royapuram Hospital,
Madras

and

T. KRISHNASAMI, L.M.P., I.M.D.
Military Sub-assistant Surgeon

THE presence of small intracellular bodies were first noted by Donovan (1905) in a case of granuloma occurring in the mouth. He had frequently noted the occurrence of this organism in cases of granuloma inguinale. As they appeared to undergo intracellular multiplication he looked upon them as protozoa, but confessed he was unable to put them into any definite group. Subsequent workers particularly Walker (1918) and, more recently, Goldzieher and Peck (1926) have pointed out that the Donovan body is not protozoal. Walker succeeded in cultivating an organism, a capsulated diplococcus which he believed to be identical with the Donovan body. It was often bacillary in shape, sometimes coccoid and when appearing inside cells seemed to possess a capsule. He therefore concluded that the organism belonged to the mucosus-capsulatus group. Subsequent workers following modern nomenclature called it *Klebsiella granulomatis*. The organism was held to be allied to the capsulated bacillus of rhinoscleroma and the similarity of the lesion to rhinoscleroma was put forward. Other workers particularly MacIntosh (1926) have confirmed the frequent presence of the Donovan body in granuloma. He experimentally inoculated a volunteer with ground-up material and produced an ulcer which healed subsequently. Campbell however was unable to confirm these results. He cultured the organism on Sabouraud's medium and inoculation experiments were entirely negative. De Monbreun and Goodpasture (1931) in subsequent experiments claim to have transmitted the disease to a monkey by inoculation of tissue containing the organism. A small nodule developed at the site of inoculation and the organisms were demonstrated inside the cells. The question of the experimental transmission of a disease by transplantation of pathological tissues is always

(Continued from previous column)

were found in culture in twelve and were isolated in pure culture in ten cases. Contamination with other organisms gave rise to difficulties in isolation in the other three cases.

open to the objection, as Campbell rightly pointed out, that other organisms present might be included. Inoculated tissues might be slowly absorbed and generally provoke a foreign body reaction, and any included organism, particularly intracellular forms, might be recovered at a later period; such a phenomenon is well known in the case of *M. lepræ*.

In the present study it was found that the organisms could be easily demonstrated in smears taken from the surface of ulcerative lesions. In cases where healing had occurred as a result of treatment, they were difficult to demonstrate. Material for examination was taken only after the ulcer had been cleaned by a few days' saline dressing. A loopful of the serous discharge was spread evenly on a slide by means of a platinum loop so that the large mononuclear cells and leucocytes were left intact. The film was then fixed by heat and stained by Gram's method or one of its modifications. The organisms appear as small Gram-negative plump cocco-bacilli about 1.5μ in length by 0.6 to 0.8μ in thickness. They are not well stained by methylene blue or Leishman's stain. Sometimes forms almost coccoid in shape are met with. The most common forms are bacillary in shape with a tendency to bipolar staining. Dumb-bell forms also occur, but all these are of the same size. The organisms are found in clumps, most often extracellular and surrounded by a clear space of some unstained material. Intracellular forms are found in the mononuclear cells or in polymorphonuclear leucocytes. Inside the cells the outlines of the organisms are not clear and they appear to be surrounded by an unstained empty space which looks like a vacuole or a 'foamy' area in the protoplasm. No true capsule is formed and none can be demonstrated by capsule staining, but they appear as if surrounded by some mucinoid material. The occurrence of intracellular clusters which are feebly stained, with disintegration of the cell suggests intracellular multiplication. Extracellular forms, however, are more common. In some smears, where the serum has been fixed by heat, all the organisms and cells may appear as if surrounded by capsules, but this is evidently the result of fixation. The shape and general appearance, and the presence of bipolar staining suggests a resemblance to Ducrey's bacillus, but chain forms are never met with. The foamy degeneration of the cell is shown in photomicrograph I, while vacuolation is shown in photomicrograph II. It is difficult to decide whether these appearances are due to phagocytosis. The organism is non-acid-fast, is Gram-negative and is easily stained by weak carbol fuchsin. In our study of fifteen cases the intracellular forms of the organism were found in ten cases while four of the remaining five showed extracellular forms. In one case, healing had occurred and no organisms could be demonstrated in smears. Aspiration of the unruptured lesion in the last case showed

the organism in small numbers. In histological sections the organisms are difficult to demonstrate if stained with hæmatoxylin, but if the tissue is fixed in alcohol and stained by Weigert's modification of Gram's stain, they can be demonstrated in the swollen endothelial cells of the capillaries.

Photomicrograph I.—Donovan bacilli inside a mononuclear cell which has burst. Note the degeneration of the protoplasm and the appearance of the organisms—coccoid, dumb-bell and bacillary forms ($\times 2,000$).

Photomicrograph II.—Donovan bacilli inside a cyst in a mononuclear cell ($\times 2,000$).

Cultivation.—For purposes of cultivation small pieces of tissue were scraped out and inoculated into various media, after the ulcer was clean. The media that were used, were plain agar, broth, serum agar, maltose agar, lactose agar, glucose agar, Crowe's medium, blood-streaked agar, Norris' medium and defibrinated rabbit's blood mixed with agar, as for Ducrey's bacillus. Primary cultures commonly

show *Staphylococcus albus* or diphtheroids which overgrow the other organisms. It was found that Norris' medium was of great use for primary culture, since all the colonies were extremely small, and there was no danger of overgrowth. Growth occurred quite well on blood agar and on chocolate agar though not quite so profusely as on maltose agar. The hæmophilic tendency that is shown by Ducrey's bacillus is not present, since the organism grew well on media which did not contain blood. Subcultures on broth were used before further differentiation. Growth was profuse on lactose agar, but no growth occurred on glucose agar or on serum agar.

Out of the fifteen cases studied cultures could not be carried out in two cases, as they left the hospital. In one case extensive healing had occurred and the organism could not be demonstrated in smears, but was isolated in cultures. In one case contamination with a coliform organism gave rise to difficulty in culture. In two cases the organisms were recognized in cultures but could not be isolated owing to contamination with *B. proteus* in one and *B. pyocyaneus* in the other.

Cultural characters.—On Norris' medium the colonies in 24 hours were glistening, convex, transparent, and extremely small, being invisible to the naked eye but appearing under the lens as pin-points. They were just visible in 72 hours. Under the lens there was a slightly wavy border and a central translucent boss. The surface was smooth and shiny, but gradually grew dry and slightly granular. On media containing blood however the colonies were much larger, varying in size from 0.3-0.4 mm. in 24 hours and appearing as low convex, rounded, shiny areas which gradually grew somewhat opaque. There was slight hæmolysis. On plain agar and maltose agar in subcultures the colonies were still larger (the size of a pin-head) in 24 hours, having a mucoid translucent appearance and showing a tendency to confluence. The growth was profuse and gradually grew more opaque and somewhat yellowish-brown in colour. On maltose in old cultures a tendency to form a crenated border was noticeable. On broth there was a slight uniform turbidity in 24 hours and a slight deposit appeared in three days. Pellicle formation was absent, and there was little surface growth. There was a characteristic odour. In all cases the colonies were soft and in young cultures easily emulsifiable, but they gradually grew slightly dry and sticky. The organisms retained their viability on Norris' medium for about fifteen days. They died out much more rapidly on maltose agar and plain agar. Growth was best at blood heat, and under aerobic conditions.

Morphology.—Young strains isolated were non-motile, but at lower temperatures sluggish motility was observed, especially in subcultures. The organism is a non-acid-fast, Gram-negative,

small, somewhat plump cocco-bacillus, slightly oval or fusiform in shape with slightly bulging sides. Most strains show a tendency to bipolar staining. There is no evidence of the presence of a capsule on staining either by Malone's or Hiss's method, though the staining is rather indistinct with young cultures, particularly with methylene blue. Dumb-bell forms appear to be merely an exaggeration of the bipolar staining and might be preliminary to division. The organism is very small, about 1.5μ in length by 0.6μ to 0.7μ in thickness. Coccoid forms met with in smears are not common in culture unless degeneration has occurred. Metachromatic granules are absent. Spore formation is absent. In general there is a great resemblance to the morphology of *B. ducrey*. The cultural characteristics of the two organisms however show marked differences, especially in the hæmophilic tendency and mode of growth. Chain forms, which are characteristic of Ducrey's bacillus, are not usual in this organism.

Biochemical reactions.—No fermentation occurred in lactose, dulcitol and mannitol; the other fermentation reactions are shown in the table below:—

TABLE

Serial No.	Glucose	Saccharose	Maltose	Salicin	Litmus milk
1	A	A	A	A	..
2	A	A	A	A	A, no clot
3	A	?	A	A	..
4	A	?	A	A	Faint A
5	A	A	A	A	Faint A
6	A	A	A	?	..
7	AG	A	A
8	AG	A	AG	A	A, slight clot

Two strains were studied regarding their power to ferment other carbohydrates. The organism was found to ferment fructose, lævulose, galactose, raffinose, dextrin, arabin, and xylose. Inulin, inositol and adonitol were unaffected. The Voges-Proskauer reaction was negative and indol formation was absent.

Pathogenicity.—Subcutaneous inoculation into white rats was followed by rapid necrosis with the formation of a chronic ulcer, which gradually healed. In guinea-pigs a more chronic reaction occurred. These will be discussed in the next part of our studies.

Nomenclature.—The name *Calymmatobacterium granulomatis* suggested by Aragao and Vianna (Karsner, 1926), and the allocation to the group *Klebsiella* are both incompatible with the structure and relationships of this organism. In view of the morphological resemblance to Ducrey's bacillus and the uncertainty of the grouping of Ducrey's bacillus it is suggested that the name *Bacillus donovani* be applied.

Summary.—The presence of the Donovan body in fourteen out of fifteen cases studied confirms the findings of numerous observers of

BACILLÆMIA IN LEPROSY

By JOHN LOWE, M.B., CH.B.

Research Worker under the British Empire Leprosy Relief Association (Indian Council), Calcutta School of Tropical Medicine

THIS subject is one to which considerable attention was paid in the past. We have traced about eighty references to this subject in the literature of leprosy, most of the articles being written between 1890 and 1916. This interest in the subject was stimulated by the fact that many leprosy workers considered it possible that leprosy was transmitted by biting and blood-sucking insects; if lepra bacilli could be found in the circulating blood the theory of insect transmission would receive some support. During recent years this transmission theory has fallen into the background (though it has not been finally disproved) and, consequently, interest in bacillæmia has somewhat declined.

The matter was also studied in connection with the possibility of congenital infection of the fœtus *in utero* by the blood of leprosy mothers, and lepra bacilli have been reported in the placenta, in the blood of the umbilical cord and in the internal organs of still-born

(Continued from previous page)

the close association between this organism and the disease. In ten out of twelve cases an organism resembling the Donovan body has been isolated in pure culture. It is suggested that this organism, which is a small bacillus showing bipolar staining, is identical with the Donovan body and the name *Bacillus donovani* is also suggested. The morphological resemblance of this organism to *B. ducrey* is brought forward. Animal inoculations show that this organism is distinctly pathogenic.

The writers are greatly indebted to the officers in charge of the venereal clinics at the General and Royapuram Hospital, Madras, for their kind co-operation in making this investigation possible. The bacteriological media were all supplied through the kindness of Lieut.-Colonel H. H. King, I.M.S., Director, King Institute, Guindy, to whom the writers tender grateful thanks.

The photomicrographs were all taken by Mr. Solomon, photographer, King Institute, Guindy, to whom thanks are due.

children [Chujo (1916), Sugai and Mononobe (1913), Rodriguez (1926), Pineda (1927)].

There is no doubt that bacilli enter the blood stream. The occurrence of multiple lesions in various parts of the body can only be explained by the bacilli being conveyed in the blood. This does not mean that the blood of leprosy cases normally shows bacilli, for bacilli may only enter the blood stream very occasionally and only in very small numbers. The possible means by which bacilli enter the blood are (a) by the lymph vessels opening by the lymphatic duct into the left innominate vein, (b) by the erosion of a leproma into a blood vessel, and (c) by infected wandering histiocytes entering the blood stream. Which of these three means is the most important it is difficult to say, for there is little evidence on this point. Lepromata normally show little tendency to erode into blood vessels, so the two other modes of entry seem more likely.

Recently, interest in bacillæmia has been somewhat revived by the writings of certain workers who claim to find bacilli in the blood of early cases of leprosy and even of 'contacts', and who have recommended blood examination for bacilli as an important aid in diagnosis and even as the best method of diagnosis.

Brief survey of the literature

It is impossible here to survey thoroughly the mass of literature on the subject of bacillæmia. We will here refer to only the more important publications.

The technique used by different workers varies. Some workers have used the thick-film method, puncturing an apparently unaffected area of skin, making a thick smear on a slide, drying, de-hæmoglobinizing with dilute alcohol or distilled water, and staining by the Ziehl-Neelsen method. Other workers have taken the blood from a vein, separated the red cells either by sedimentation or by hæmolyzing agents, and examined the white cell deposit. Two methods have been commonly used, those of Crow (1912) and Rivas (1912).

The technique of Rivas is as follows:—

Collect 0.1 c.cm. to 1 c.cm. of blood from a vein in 5 c.cm. to 20 c.cm. of 2 per cent acetic acid solution, in which the erythrocytes are dissolved. The mixture is centrifugalized for 15 minutes. The sediment is spread on a slide, dried, stained and examined.

Crow's technique:—Take 5 to 10 c.cm. of blood from a vein into a sterile test tube containing 5 to 10 c.cm. of 2 per cent sodium citrate in normal saline. Mix thoroughly, and leave overnight in an ice box. The next day there will be found three layers, at the bottom a thick layer of red cells, in the middle a thin layer of leucocytes, and above the serum and citrated saline. Make thick smears by removing some of the leucocyte layer in a capillary pipette. Dry, de-hæmoglobinize any red cells.

present by treating with distilled water for 15 minutes. Dry again, stain and examine.

Results reported

In 1896 Stephan reported a case of maculo-anæsthetic leprosy in which *M. lepræ* were found in all of sixty thick smears, thirty from macular lesions and thirty from apparently healthy skin, and he considered that this proved that the bacilli were free in the blood stream. Various later workers criticized this conclusion, for they said it merely showed that bacilli were present in the skin and not necessarily in the general circulation. Most of the workers after this took the blood from a vein.

Doutrelepoint and Wolters (1896) found bacilli in the blood of all cases of lepra reaction and not in others. Several other workers have verified this. Babes (1901) failed to find bacilli in the blood in lepra reaction but did find them in one non-febrile case.

Crow (1912) reported 21 positive findings in 24 cases. Later he reported 8 positive findings in 10 cases after taking all precautions to prevent false positives. Takasawa (1911) reported 12 positive out of 31 cases. Marchoux and Bourret (1909) failed to find any bacilli in the blood stream. M. Chujo (1911) reported 14 positive findings in 27 cases, the largest number of bacilli being 12 and the average 3. Half the organisms were found free and half inside leucocytes and large mononuclears. Ohashi (1911) reported 80 per cent positive findings in lepra tuberosa and 22 per cent in lepra nervosa. Honeij (1915) reported, in 28 examinations of 16 patients, 9 positive results, 3 questionable, and 16 negative. Mitsuda (1911) in 31 cases of lepra tuberosa found 12 positive. Two cases of lepra reaction showed large numbers of bacilli. Iyengar (1919) reported finding lepra bacilli in the blood of 4 out of 10 cases of nodular type, 1 out of 20 of anæsthetic type, and 2 out of 10 of mixed type. Two nodular cases showed bacilli in the blood from the skin, but not in the nodules. Rivas and Smith (1914) using the thick film method in three cases found many bacilli in the blood from the lesions and a few in the blood from the fingers and toes which were unaffected. Blood from veins also showed a few bacilli. They considered this as a very definite proof of bacillæmia. Such reports can be multiplied indefinitely.

The first really critical examination of the subject is that of Hollmann (1916). After a brief survey of the literature he reported on the examination of 22 cases by the technique of Crow and of Rivas. The blood was taken from an arm vein and the puncture made through apparently healthy skin. Not trusting to appearances, after taking the blood from the vein he made scrapings and smears from the puncture hole in the skin. He reported as follows:—Of 17 nodular cases six showed bacilli in the slide made from the blood. Of 5 anæsthetic cases none showed bacilli. The largest

number of bacilli seen was 7 and the smallest 1. Of the six cases (all nodular) giving positive results in the blood, 5 showed bacilli in the apparently normal skin at the site of puncture. Hollmann said 'It is possible that the needle puncture may have become infected with acid-fast bacilli from the blood when the needle was withdrawn'. He does not seem to have seriously considered the other explanation, namely that the blood was infected by the needle which had passed through infected skin. The explanation seems to us to be a far more likely one. Although the evidence seems fairly clear, the logical conclusion, that many positive results reported are false positives due to infection of the blood from infected skin at the site of puncture, does not seem to have been drawn.

Markianos (1931) using the thick film method found that bacilli were found only when the puncture was made through affected skin. Unaffected skin showed no bacilli in the thick blood drop. He considered that positive findings in the film were due to the blood washing out bacilli from the lymph spaces in the infected skin at the site of puncture. Nevertheless he considered that the thick film method of bacteriological examination of leprosy lesions was a useful procedure in diagnosis. Mitra (1932) using the thick film method reported positive findings in unaffected skin in 21 out of 26 cases. He described the thick film method as a new method of diagnosis of leprosy. Sardjito and Sitanala (1932) using the thick film method in unaffected skin found bacilli in 35 out of 38 cutaneous cases, and in 3 out of 14 nerve cases. Of 129 healthy contacts 6 gave positive results, in one case as many as 50 bacilli in one microscope field. They found that the thick film method taking the blood from a finger showing no leprosy lesions gave a higher percentage of positive findings than either nasal examination or examination of the skin of the ear lobe.

Discussion of these findings

It will be seen that these findings vary so tremendously that it is very difficult to assess their value. There are so many difficulties and fallacies. The principal factors causing these differences in findings are:—

1. *Variation in the type and stage of the disease.*—Bacillæmia is commonly reported in cutaneous leprosy and rarely in nerve leprosy. It is reported to be much more common in cases of reaction than in other cases.

2. *Differences in technique.*—Some methods involve the examination of the deposit from 0.1 c.cm. of blood. Other methods of 10 c.cm. of blood. Results naturally vary.

3. *The difficulty of avoiding contamination of the blood from infected skin at the site of puncture.*—This difficulty is very great and we believe that it probably accounts for many of the positive results reported. In cases of leprosy, areas of skin which appear normal often show definite lesions and numerous bacilli

on pathological examination. Several such cases have been reported by Lowe and Christian (1932) and one such case by Muir (1932). In a case of leprosy, it is impossible to tell from mere inspection whether skin is affected or not. The only sure method of excluding skin infection is to cut out the piece of skin for section and this is not a practical procedure in many cases. One has to rest content to make slit scrapings and smears of the skin at the site for puncture. When this is done, as reported by Hollmann (1916), it is found that nearly all the cases showing bacilli in the blood show bacilli in the skin at the site of puncture, and thus grave doubt is thrown on the accuracy of the findings of bacilli in the blood.

Recent publications claiming to have demonstrated bacillæmia by thick film methods ignore the possibility of the bacilli coming from the skin and the only precaution taken to prevent this is naked-eye inspection. 'The skin appears normal' is the usual report but this is absolutely unreliable. We have seen dozens of 'normal' areas of skin in which millions of acid-fast bacilli could be found. In fact in many cases of cutaneous leprosy it is difficult or impossible to find unaffected skin in a site suitable for puncture.

The failure to realize these facts makes most of the past work on bacillæmia of very doubtful value. Since blood examination has been recommended as an important aid in diagnosis, the matter is not purely an academic one. It therefore seems desirable that a fresh investigation of the subject should be made, taking all precautions against false positive findings, examining cases at all stages of the disease, and using as standard the method which is found to give the greatest number of positive findings.

Investigation of the thick blood film method of finding Hansen's bacillus

Experiment 1.—One hundred cases of neural leprosy were examined by the thick film method, a finger being pricked by a needle to make the film. In not a single film were any acid-fast bacilli found.

Experiment 2.—Fifty cases of cutaneous leprosy were similarly examined. Seventeen showed bacilli in the thick film. These were all advanced cutaneous cases. Of these seventeen, ten showed visible skin lesions in the skin of the finger, and in the other seven, smears taken from the skin at the site of the prick showed in every case many more acid-fast bacilli than were found in the thick film.

These two experiments show quite clearly that the thick film gives positive results when the skin at the site of the prick is leprosy, and that naked-eye inspection of the skin is not a reliable method of detecting slight leprosy skin lesions. The slit smear method used in the same site shows far more bacilli than the thick blood film method and this suggests that the bacilli in the thick blood film come from the

skin at the site of the prick, and not from the circulating blood.

A further small test of this method was made.

Experiment 3.—Ten cutaneous cases were chosen all being of the milder type (C_1 or C_2) and all showing no outward sign whatever of leprosy lesions of the finger. Thick films were made from the finger and also at the same time slit smears from the skin about one quarter of an inch away from the site of the prick.

Of 10 cases, 7 showed bacilli in the thick blood film.

Of 10 cases, 8 showed bacilli in the slit smear.

None showed bacilli in the thick film without showing them also and in far greater number in the slit smear.

This experiment showed fairly clearly that the bacilli came from the skin and not from the circulating blood; but to test the matter still further another experiment was done.

Experiment 4.—In the above seven cases showing bacilli in the thick blood film, the venous blood was taken and examined for bacilli by the technique to be described later. In only one case were bacilli found. We think that this shows fairly conclusively that in most cases bacilli found in thick blood film come from the skin.

Examination of the venous blood for bacilli

Technique.—It is not easy to develop a suitable technique. An examination of the literature on tuberculosis reveals the fact that dozens of different methods have been recommended by different workers. This is a clear indication that there is no one simple reliable method. A suitable method should use a fairly large quantity of blood and reduce it to a small amount of residue. The chief difficulty which is encountered is the precipitation of albumen which occurs when acid or alkali is added to destroy the cells.

The following method, which we have adopted after testing many different methods, has given us the most satisfactory results. With a sterile syringe and needle the antecubital vein is punctured in an area of apparently healthy skin and 4.8 c.cm. of blood are drawn off and evacuated at once into a sterile centrifuge tube containing 1.2 c.cm. of 5 per cent sodium citrate. The tube is shaken to mix the two fluids, and then centrifuged thoroughly. The supernatant fluid is then carefully removed with a sterile capillary pipette, and the blood cells are left. To this residue about 7 c.cm. of 25 per cent alcohol is added and the tube thoroughly shaken. This de-haemoglobinizes the red cells. The tube is then centrifuged for ten minutes, and the fluid is again pipetted off. Only the white cells are now left. To this residue add 1 c.cm. of 10 per cent antiformin and shake thoroughly. This dissolves the white cells and at the same time precipitates some albumen. Leave the tube standing for 5 to 10

minutes until the cells are completely disintegrated. Then add about 6 c.cm. of 30 per cent alcohol, mix thoroughly and centrifuge again. Pipette off the fluid. A small amount of white residue is left at the bottom of the tube. This consists of cellular debris and bacilli if present. Smears of this residue are made with a platinum loop and a little egg albumen on a microscope slide, fixed by heat, stained and examined. Two hundred fields were carefully examined in every case.

Experiment 5.—Twenty-three cases of neural leprosy were examined by this technique. In two cases acid-fast bacilli were found, in one case only 2, and in the other case 3.

Experiment 6.—Fifty-one cases of cutaneous leprosy were examined by this technique. In 28 cases bacilli were found. These were nearly all marked cutaneous cases and the number of bacilli was very small.

This experiment shows that this method of examination of venous blood gives a far higher percentage of positive findings than does the thick film method. This is only what one might expect since a far greater volume of blood is examined. The question still remains however as to the possibility of these bacilli getting into the blood from the skin at the site of vein-puncture. This matter was investigated.

Experiment 7.—In 21 cases all showing bacilli in the blood taken from a vein by the above technique, slit smears were made of the skin at the site of vein-puncture. It should be noted that in all these cases the skin at the site of vein-puncture appeared perfectly normal on inspection and palpation. Of the 21 cases, 15 showed bacilli in the skin; in several cases they were quite numerous and in every case more numerous than in the film made from the venous blood. It therefore appears quite probable that some of the positive findings in experiment 6 are false positives caused by a few bacilli in the skin contaminating the needle and the blood from the vein.

Conclusions

From these experiments we draw the following conclusions:—

1. The finding of bacilli in the circulating blood of cases of neural leprosy is very rare.

2. The finding of bacilli in the circulating blood of cases of cutaneous leprosy is commoner.

3. The thick film method of detecting bacillæmia in the blood is extremely unreliable, nearly all the positive results reported being false positives due to the prick being made in leprotic skin.

4. Examination of the venous blood by a concentration method as described is much more reliable, showing bacilli very occasionally in neural cases, and commonly in cutaneous cases, particularly in marked cutaneous cases,

but it is probable that some of these findings are false positives.

5. Examination of venous blood for lepra bacilli is a complicated and difficult procedure and quite unnecessary for diagnosis.

6. Other methods of bacteriological examination particularly skin examination by the 'slit' and 'clip' methods are far easier and far more reliable than blood examination.

One very interesting point to which we have previously referred but which the present investigations have demonstrated very clearly is the very frequent finding in definite cases of leprosy of acid-fast bacilli in apparently unaffected areas of skin. In cases of cutaneous leprosy the involvement of the skin is very much more extensive than the clinical lesions would indicate. In practice we find that in marked cases of cutaneous leprosy, although the visible lesions are confined to certain areas of the skin, yet practically all the skin of the body may be involved; hence it is difficult or impossible to puncture a vein through unaffected skin.

THE MECHANISM OF IMMUNITY IN MALARIA

PROOF OF THE PHAGOCYTOSIS OF MALARIAL PARASITES BY LARGE MONONUCLEAR CELLS IN MALARIA

By H. STOTT, M.D. (Lond.), F.R.C.P. (Lond.),
D.P.H. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology, King George's Medical College,
Lucknow

IMMUNITY in protozoal diseases such as kala-azar and malaria differs markedly from immunity in bacterial diseases, such as typhoid infection, in that the evidence of comparable toxin production and the demonstration of antibodies in the plasma by serological tests is not yet accepted.

On the other hand, the reticulo-endothelial system immediately falls under suspicion as the main means of destroying the parasites of kala-azar and of malaria, through the mechanism of phagocytosis, by reason of the great enlargement of the spleen and to a lesser degree of the liver in these two diseases, and by reason of the associated rise in the large mononuclear count in the blood.

In kala-azar, little or no acquired immunity develops and the natural course of an untreated case is rapidly towards death; but all laboratory workers are aware of the phagocytosis of kala-azar parasites by the reticulo-endothelial monocytes of the spleen, and of the occasional appearance of such parasite-laden mononuclears in the blood.

In malaria, some degree of immunity or tolerance is acquired after years of exposure to endemic infection; this is indicated by the diminution of the spleen, parasite and fever rate as the age of those exposed to infection throughout life increases. In malaria, as in Kala-azar, it has long seemed probable that a hypertrophy of the reticulo-endothelial system results in the active phagocytosis of malarial parasites and in their rapid destruction. This destruction is even more complete than with kala-azar, whence the relative innocence of malarial infection. Fortunately, the malarial parasite produces an easily recognized pigment and thus furnishes abundant proof of the phagocytic activity of the reticulo-endothelial cells in severe malaria in that smears from the spleen, liver and bone-marrow show phagocytosis of black or of yellow-brown malarial pigment (as was obvious in my case recorded below) whilst smears from other body organs (e.g., salivary glands, pancreas, kidney, thyroid, heart, etc.), show no such massive collections of pigment within their fixed tissue cells. The reticulo-endothelial tissues in a fatal case of acute malaria indeed provides a natural analogue of the 'blockage' of the reticulo-endothelial system with injected pigments and dyes.

Further, pigmented large mononuclear cells are not infrequently found free in the peripheral circulation in severe and chronic malaria.

But whilst the proof of pigment phagocytosis both in the fixed cells of the reticulo-endothelial system and in the peripheral circulation is obvious, the proof of the existence of malarial parasite phagocytosis in man has hardly yet been made clear. In both bird and monkey malaria experimental proof already exists of the active phagocytosis of malarial parasites in liver and in spleen smears and also, in heavy infections, in the peripheral blood.

But, until December 1932, very few cases have been recorded in which malarial parasites undergoing phagocytosis have been observed in the blood in human malaria. Indeed Chopra and Sen in reporting 'A fatal case of severe malignant tertian malaria' in the *Indian Medical Gazette* of December 1932, in which they observed 'a heavy phagocytosis of the parasites' by the large hyaline and polymorphonuclear leucocytes in the blood of a human subject half an hour before death, note that this phenomenon 'has not apparently been seen by any other workers, except by Knowles and Das Gupta (1931) who only once encountered scanty phagocytosis in a malignant tertian infection'.

But since the proof of the recognition of malarial parasite phagocytosis in man is so important a step forward in the understanding of the mechanism of immunity in malaria, I am tempted to place the following two examples which I have observed, one in 1919 and one in 1932, on record. The first case showed a small malignant tertian ring in the cytoplasm of a large mononuclear cell which I found in the blood smear of a soldier with severe malignant malaria in the brigade laboratory, Bannu, North-West Frontier of India, in 1919, and a copy of the diagram I then made is reproduced as figure 1. My 1932 case is described below:—

Fig. 1.

CLINICAL FEATURES

In December 1932 a well-built deeply-jaundiced male, Pahari Hindu of some 25 to 30 years, was found unconscious in a railway carriage in which there was also a dead body. The Police brought him to King George's Hospital, where he was admitted with deep jaundice in a cold and collapsed condition with a temperature of 96.4°F., a pulse rate of 98, and respirations at 22. The liver was enlarged three fingers below the costal margin and was soft and tender. The spleen was also soft and markedly enlarged. The blood was taken at 2 P.M., ten grains of quinine were given intravenously at 3 P.M. and he died at 4 P.M. in complete coma.

BLOOD-FILM EXAMINATION

Variety of parasites present.—99.5 per cent of the blood parasites were in the form of small malignant tertian rings, including many 'accollé' forms, whilst 0.5 per cent malignant tertian sporulating bodies were noted in 2,000 parasites counted. No gametes were observed in many thousands of fields examined. No large benign tertian types of rings were observed, and no benign pre-sporulating amoeboid forms. In some 15 malignant tertian sporulating bodies the merozoites numbered 14, 7, 6, 10, 7, 11, 16, 17, 7, 16, 14, 14, 15, 17, 12, with an average of 12 merozoites per sporulating body. The small rings varied slightly in size. There were many examples of multiple infections in a single red cell. The following table shows the percentage of infected red cells showing multiple infection:

M. T. Rings in the R. B. C.	INFECTED R. B. C'S. COUNTED	
	Actuals	Per cent.
1	1,384	82.5
2	236	14.0
3	35	2.2
4	12	0.7
5	1	0.1
Sporulating bodies	9	0.5
	<hr/> 1,677	<hr/> 100.0

Many rings had two chromatin dots, in one red cell three rings were seen each of which had two chromatin dots. In another red cell no less than six rings were seen, most of which had two chromatin dots. These points are brought out in the diagrammatic composite field shown as figure 2. The blood smear diagnosis therefore was an intensely heavy infection with asexual malignant tertian parasites. The clinical diagnosis was an algid type of acute malignant malaria with jaundice.

Fig. 3.

Number of parasites present.—Under the microscope every field showed a very heavy infection with parasites. At first glance it appeared as though some 50 per cent of red cells were infected, but on counting 5,000 successive red cells 34 per cent were found infected and 66 per cent uninfected.

The red cells.—These were normal in size and shape. There was no marked evidence of any rapid red-cell production or degeneration, but a few nucleated and some polychromatophilic red cells were seen. The total red cells appeared greatly decreased in proportion to the white cells present there being 65 white cells amongst the 5,000 red cells examined, but this count was made along the free edge of the film.

The white cells.—The differential count of 2,000 white cells showed, polymorphonuclears—27 per cent, large mononuclears—16 per cent, lymphocytes—56 per cent, and eosinophiles—1 per cent.

The great increase in the combined large mononuclears and small lymphocytes was very obvious. Amongst the lymphocytes were encountered a number of mononuclears of a size slightly larger than a polymorphonuclear

cell but with a large round or oval nucleus and a narrow strip of clear blue protoplasm. Many Turks' irritation cells were present. The serum gave an immediate direct positive van den Bergh's reaction.

Phagocytosis of parasites

This film contained so many parasites that it was distributed to a class of some fifty students and it was also examined by several workers in the laboratory without the mononuclear phagocytosis being observed. Once however the first example had been identified and attention was thus diverted to the blood phagocytes—many further examples were recognized. The first example seen (figure 3) showed a large mononuclear phagocytosing a sporulating body, the area around which was clear, colourless and well defined, and of the same size as the surrounding red blood cells.

Fig. 6.

Near it and within the same mononuclear was a pink-stained red blood cell of the same tint and size as the extracellular red cells. Five masses of pigment were also seen within the cloudy cytoplasm of the cell.

A second example (figure 4) showed the process of intracellular digestion further advanced. The clear circle of the size of a red blood cell

Fig. 4

obvious in figure 3 had disappeared and a faint halo only surrounded the grouped spores the staining of which was less defined than in the previous example. An independent small ring was also seen in the cytoplasm. Another mononuclear (figure 5) showed the spores apparently scattered throughout the cell cytoplasm and their differential staining was even more obscure. In figure 6, a red cell containing two

Fig. 5.

Fig. 7.

small rings had been phagocytosed. This perhaps is the usual stage previous to the finding of small rings in the cytoplasm though perhaps it is just possible that young 'accollé' parasites free in the blood may be phagocytosed and develop in the large mononuclears to ring forms. The diagrams were drawn from cells actually seen. The shape of the large mononuclear phagocytes was usually somewhat flattened oval, and the outline slightly wavy. The nucleus was usually elongated or somewhat indented. The cytoplasm was hazy and stained somewhat indefinitely whilst in it were often vacuoles, pigment and granular debris, the origin of which it was only possible to surmise. In one cell (figure 7) the semi-digested remains

Fig. 8.

of a sporulating body could just be made out. No parasites were observed inside the polymorphonuclear cells, but in them pigment and granular debris was not uncommon (figure 8).

Fig. 2.

POST-MORTEM AND MICROSCOPIC SECTION REPORT

All the tissues were deeply jaundiced. The enlarged liver weighed 63 ounces, and the enlarged soft spleen weighed 15 ounces. The other organs were normal.

Microscopic sections of the spleen, liver, lung, brain, adrenals, heart, testicle, kidney, pancreas and salivary and thyroid glands were examined, but proved of interest only in that pigment was found outside the blood vessels only in those organs in which the reticulo-endothelial cells exist—e.g., pigment was scattered in large amounts throughout the spleen and also through the liver, not in the hepatic cells themselves but closely packed in the Kupffer stellate cells. The lung showed mononuclear phagocytes packed with pigment in the alveoli. The brain and adrenals showed some small amount of extra-vascular pigment, whereas the heart, testicle, pancreas and salivary glands were practically pigment free. The capillaries of all organs were full

of parasitized red cells and of pigmented mononuclears. The pigment was of two kinds (1) coal black and (2) yellowish brown which was greater in total amount. The kidney sections showed some glomerular nephritis and blood casts.

Three other cases showing parasite phagocytosis in human blood

Major Fitzgerald, I.M.S., who has had much experience of practical blood smear work in Assam, informs me that he observed two cases in which he saw malignant tertian rings within large mononuclear blood cells. Both cases showed a heavy infection of small malignant rings within the red cells and also numerous sporulating bodies in the peripheral blood which latter mainly attracted his interest. Both patients were severely ill with high fever and stertorous breathing and died in coma within a few hours of admission. The clinical diagnosis was cerebral malaria. As most patients in Assam the spleens were enlarged, but there is no recollection as to whether an enlarged liver and hæmolytic jaundice was present. I have consulted four other medical officers of special experience in malarial film work in the United Provinces but they have not observed this phenomenon. Chopra and Sen's case was clinically similar to the above; he died in coma the day after admission with fever. The total red cells were 4,680,000 of which 54 per cent were infected; the infection rate later rose to 67 per cent. Blood, two hours and again half an hour before death, showed parasite phagocytosis—chiefly schizonts by large mononuclears and polymorphonuclear cells. Thompson and Robertson in their *Protozoology* (1929) figure a polymorphonuclear leucocyte containing two mature malignant tertian segmenting forms and remark on page 52 that 'The large mononuclears, especially those of endothelial origin, are highly phagocytic and may be seen in the peripheral blood containing numerous masses of pigment. The polymorphonuclears too are also actively phagocytic and may actually engulf pigment or complete schizonts'.

Craig, C. F. (1909), in his *Malarial Fevers* says 'the endothelial cells of the liver are found in the peripheral circulation acting as phagocytes in only the most pernicious cases of malaria, but in the liver these cells are actively phagocytic'. In one or two instances I have observed entire plasmodia within coarsely granular eosinophiles.

I am much indebted to Lieut.-Col. Sinton, V.C., I.M.S., in charge of the Malarial Bureau of the Central Research Institute, who has himself observed this phenomenon of phagocytosis of malarial parasites in the peripheral circulation, for the following two references.

Firstly, Marchiafava and Bignami in their historic work entitled 'The parasites of malarial fevers', 1894—write (page 180) 'The fact that in the dangerous infections one frequently meets with blood-corpuscle-laden cells, and especially with large leucocytes containing brassy red

dissected up the peritoneum similarly to what occurs in a large broad-ligament cyst. The transverse and descending colon formed part of its wall. The peritoneum gave way above the uterus towards the right side, where the edge of a necrotic placenta appeared. The foetus was easily removed. Apart from a condition of pes calcaneus, it was well formed and weighed 5½ lbs. It was of course dead. A quantity of liquor amnii, much thickened with meconium, vernix and debris, escaped. The placenta and part of the necrotic sac was removed without difficulty. The remainder was closed over and the abdomen closed without drainage. The patient died 5 days later of peritonitis, probably on account of infection from the colon.

It is considered that in this case drainage should have been through the posterior fornix as a final step in the operation, and that the patient's life might perhaps have been thereby saved.

Tubal abortion.—Mrs. M., admitted on 30th May, 1933, for uterine hæmorrhage. She complained of bleeding from 23rd to 29th May, accompanied by pain in the lower abdomen. The pain, which was sudden in onset but not severe, was dull aching in character, varying in intensity. The bleeding was very slight for the first two days.

History.—Married 3 years; no pregnancy.

Menstrual history.— $\frac{3-4}{28}$ type, regular.

Dysmenorrhœa for the last 4 periods, with slight fever. The last period (11th to 16th May) was 10 days late. Previous periods regular.

Per vaginam: Uterus anteverted, normal in size. Right fornix hard, ovarian swelling the size of a walnut. Left fornix soft, swelling the size of a small orange. No cervicitis.

Patient admitted to hospital for observation. Slight intermittent discharge of blood continued.

Aschheim-Zondek test :—Result : weak positive on 6th June, 1933.

The patient was operated upon on 14th June, 1933, for ectopic gestation.

The pelvic peritoneal cavity contained a good deal of black blood. A tubal mole was seen protruding from the abdominal ostium of the right tube, which was somewhat enlarged and collapsed. The mole was easily expressed from the abdominal ostium by gentle pressure, leaving the tube undamaged and with only very slight oozing of blood.

The left tube was found to be closed, and its ampullary portion dilated. It appeared to be slightly inflamed. It was incised, salpingostomy being done. The patient and her husband being very anxious for a child, the right (pregnant) tube was left intact in view of the character of the left tube. A ventri-suspension completed the operation.

The patient's husband gave a suspicious history of infection and the patient was given

special treatment in view of this. She made an excellent recovery.

Ovarian pregnancy.—Mrs. C., aged 38, first seen on 26th April, 1933, for sterility; she was perfectly healthy and her pelvic organs were normal. Her last period of menstruation was on 20th to 22nd April.

A Rubin inflation of the fallopian tubes was carried out on 1st May, at a pressure of 120; both tubes were patent. Fourteen days later, when the next period was expected, the patient was seized with severe lower abdominal pain and remained two days in the nursing home. The writer happened to be out of Bombay just then and did not have the opportunity of examining her for the pain, which subsided in two days. The expected period did not arrive.

She was seen again on 31st May, with a slight uterine hæmorrhage, but no pain. She stated that, since the pain of 15th May, she could not lie comfortably on her left side.

She was not examined vaginally, as it was not thought desirable to increase the risk of a threatened abortion. She did not keep in touch with the writer, but returned on 14th June, reporting that she had miscarried on the 8th. From her description of what she passed, and the fact that she was a trained maternity nurse, I at first considered that this was probable, but on examining her I found the uterus not enlarged and a lump situated behind and to the left of it about the size of a plum, slightly tender and firm in consistency. There was pulsation between this lump and the left side of the uterus. She had a slight blood-stained discharge brownish-red in colour, and had slight pain in the lower abdomen. She was told that the condition might indicate extra-uterine gestation, was cautioned to keep very quiet, and to remain in communication with the writer. In the event of any pain or feeling of illness, she was instructed to go to the nursing home immediately.

No such developments occurred, but, under instructions, she returned on the 19th and the following condition was found :—

Slight uterine bleeding as before. Slight pain in the hypogastrium. By vaginal examination the lump to the left of the uterus was found to be enlarged to double the size noted on the 14th. She was ordered immediately into the nursing home as a case of extra-uterine gestation, and was operated on the same day.

On opening the peritoneum, there was extremely little free blood, but, on raising the sigmoid flexure, the left ovary was found enlarged to the size of a peach, deep red in colour, and with loose adhesions of blood-clot to the lateral wall of Douglas' pouch. The ovary presented exactly the appearance of a twisted ovary, or ovarian hæmatoma, clearly limited to the ovary except for the shell of blood-clot noted. There was only a little blood-stained serum in Douglas' pouch. The left fallopian

tube was absolutely normal throughout its length, its abdominal ostium being patent and entirely free from any swelling or bleeding.

On freeing the ovary, the ovarian ligament was clearly defined and tied off, and the ovary removed. Nothing else (except the appendix) was removed, as both tubes and the other ovary were quite normal. The patient made a good recovery.

The specimen was immediately examined by the operators. On incising the ovary towards its outer side, an intact gestation sac was found, deeply embedded among the blood-clot, and, on opening this, an ovum, 0.6 centimetre in length, was demonstrated. Assuming that this was an ovum of normal development, it would be scarcely a month old. Hence the questions arise: Was the patient pregnant when she missed her period on 14th May? If so, was it a second follicle which gave rise to the ovarian pregnancy and in consequence did she really have an abortion on 8th June? I am inclined to think that a menstrual corpus luteum in the left ovary was prevented from degenerating by an accidental fertilization, about the middle of May, of a second follicle in the same ovary, hence the period expected in the middle of May did not appear, and the foetus was of about five weeks' development, allowing for its being less well developed than it would be if implanted in the uterine decidua.

Repeated tubal pregnancy with twins.—It is recognized that, where pregnancy has occurred in one tube, there is a marked risk of a subsequent pregnancy occurring in the other tube, though naturally cases of this kind are scarce. The following example is of exceptional interest in view of the fact that the second tubal pregnancy presented twins.

Case.—G., was admitted under the care of another surgeon on 23rd May, 1928, with symptoms suggesting extra-uterine gestation. She was operated upon on 1st June, 1928, when a left tubal pregnancy was found and the left tube and ovary were removed.

The patient was re-admitted under the present writer on 2nd January, 1932, for pain in the lower abdomen of two days' duration with a history of having missed two periods, previous to which the periods were quite regular.

On examination, a painful swelling, small in size, was found in Douglas' pouch and on the right side of the uterus. Shortly after the examination, the patient collapsed, presenting all the signs of internal hæmorrhage. She was immediately operated upon, when a ruptured gestation sac in the right tube was discovered which was bleeding freely. Right salpingo-oophorectomy was performed. The patient made a good recovery.

The tube, on being opened, contained a gestation sac in which were two embryos of about 1½ months' development.

CONGENITAL DILATATION OF THE FETAL URINARY BLADDER

By PROBODH CHANDRA DAS, M.B.

Calcutta, India

History of the case

THE patient was a Hindu Bengali, aged 30 years, a primigravida in her seventh month of pregnancy. The abdomen was tense and appeared like full term. Fœtal parts could not be made out nor the fœtal heart sounds heard. Excess of liquor amnii was diagnosed. The labour pains soon started and after a normal easy labour lasting about twelve hours the patient was delivered of twins. The first baby was an anencephalic monster with distended abdomen and the second one was a normal female. Both of them appeared to be of seven months' size. There was a moderate amount of post-partum hæmorrhage. After a stormy puerperium the patient was discharged cured.

Post-mortem examination

The foetus was an anencephalic monster measuring 12 inches in length and weighing

Photograph showing the various organs of the foetus. V, cut end of the vagina. Uterus and vagina have been removed to get a clear view of the bladder and the ureters.

3 pounds 14 ounces. The abdomen was distended, tense and felt like a cyst. Other external abnormalities noted were absence of anus and breasts. In the region of the external genitals, there was a fleshy protrusion, of about

1 centimetre in length appearing like a penis with a slight swelling underneath which looked like a scrotum. The protrusion was later found to be the clitoris.

The abdomen was opened and about 14 cubic centimetres of clear straw-coloured fluid was drawn out of the peritoneal cavity. The abdominal wall was very thin and measured not more than 3 to 4 millimetres. The bladder was distended to the size of a foetal head and was more or less ovoid in shape with a short bulging on the upper surface (see photograph). The distended bladder occupied the major portion of the peritoneal cavity. Both the ureters were slightly distended and tortuous, specially the right one. There was one kidney, the size of an almond, lobulated and hydronephrotic, and situated on the left side. Both the ureters opened into the same kidney. No supra-renal gland was found to exist. The urethra was absent and in its place was a very fine fibrous-looking cord proceeding towards the clitoris and ultimately blending with the surrounding tissues. Behind the bladder were the uterus and vagina, normally developed. The fallopian tubes and ovaries seemed normal. The colon ended in a blind pouch and was dilated and club-shaped on account of contained meconium.

The fluid in the bladder was drawn off with a syringe and afterwards an opening was made in the bladder to inspect its cavity. The wall of the bladder was thin, excepting the most dependent portion where it was slightly thickened. The lining surface was smooth but pale. No urethral opening was found.

Examination of the fluids

The fluids were odourless; no sugar, urea, phosphates, acetone, bile pigments or bile salts were present. Further details are given in tabular form below:—

	Peritoneal fluid	Fluid in the bladder
Amount	.. 15 cubic centimetres.	70 cubic centimetres.
Colour	.. Pale yellow	Clear.
Specific gravity	.. 1006	1008.
Reaction	.. Alkaline	Alkaline.
Deposit	.. Thick whitish	Nil.
Albumen	.. Present (slight)	Present (slight).
Blood	.. Present	Present.
Rivalta's test	.. Negative	Negative.
Microscopic examination.	Nil	A few red blood cells and pus cells

Review of literature

Goldberger (1929) collected from the literature 217 cases of congenital dilatation of the foetal bladder. Jeffcoate (1931) described a case making a total of 218 cases. It is evidently a rare condition especially as a cause of dystocia. For most of our knowledge on the subject we are indebted to Spicer (1908), who dealt with the subject exhaustively.

The children affected have been mostly males. Foetal ascites has also been present in a few

cases (Gupta and Das, 1931). The condition is often associated with other abnormalities, commoner ones being spina bifida, talipes, mal-developments of the genitalia, and defects of the lower alimentary tract. Imperforate anus is a more or less constant feature. The rectum is usually absent, the colon ending in a cul-de-sac. Schwyzer quoted by Dorland (1919) stated that dilatation of the Müllerian ducts (uterus and tubes) may be associated with vesical distension.

The conditions of the urinary tract have varied from moderate degrees of enlargement of the bladder with normal ureters and kidneys to great enlargement of the bladder with bilateral hydronephrosis. In some cases complete renal atrophy is noted and in other instances there may be total absence of a kidney and a ureter. The bladder generally retains its normal shape; but there may be present one or more loculi. The bladder wall in some of the cases is very greatly thickened and in others it is extremely attenuated. An extreme degree of vesical distension with dilatation of the ureters and renal pelves is the rule.

Ballantyne (1902) thinks that two different classes of case should be distinguished, the first, in which the bladder is distended alone; and the second in which it is hypertrophied as well as distended. Spicer, however, is not convinced that there is any necessity for such a distinction. He holds that hypertrophy and dilatation of the bladder can only arise where there is actual or virtual means of exit for the contained fluid.

Ætiology.—From the point of view of ætiology, these cases could be divided into two groups, namely: one in which some form of urethral obstruction is present, and the other in which no such abnormality of the urethra is present. The cause in the first group of cases is to be found in atresia, or complete absence of the urethra. Very often obliteration of the meatus urinarius or partial defect of the urethra is present; or the urethra is replaced by a mere cellular cord (Birnbbaum, 1912). According to Dorland imperforation of the urethra is almost invariably present, although in some cases this does not hold true, and then the occlusion of that canal is produced by a valve-like fold of the vesical mucosa.

For the ætiology of the second group of cases, many suggestions have been put forward. Among them may be mentioned hypo-æsthesia or hyper-æsthesia of the bladder. It is believed that in all probability the underlying cause is an abnormality in the neuromuscular mechanism.

The fluid.—It is always clear, limpid, serous, of low specific gravity (less than 1010), and of a light citron-yellow colour. It is more or less strongly albuminous and contains practically no urea. It varies in quantity from a few grammes to six or more litres.

The origin of the fluid is easily explained if the former view of regular discharge of foetal urine into the amniotic cavity is taken into consideration, in which case an atresia or an obstructed urethra will readily give rise to a distended bladder. But it is now accepted that the foetal kidneys normally do not secrete at all, or at most nothing but water in minute quantity, and even that only during the last few days before labour. The true renal function in intra-uterine life is carried on by the placenta and according to Spicer foetal kidneys secrete only when the placenta becomes defective as an excretory organ. Most foetal abnormalities, even of the gravest nature, are not incompatible with foetal life and growth. Naturally, therefore, atresia or absence of the urethra may readily exist and the foetus, nevertheless, advances to full term and post-natal existence without experiencing any inconvenience and without having any accumulation of fluid taking place in its bladder. Jeffcoate believes that there is a definite association between the occurrence of urine in the foetal bladder and prolonged labour. On the other hand it has been stated that labour is not an important factor in stimulating urinary secretion since babies born by Caesarean section before the onset of labour have, on a few occasions, micturated within a short time of delivery.

Thus it will be seen from what has been said before, the origin of the fluid in the bladder is still a matter of dispute and no one has so far given a satisfactory explanation. Spicer believes that accumulation of the fluid in the foetal bladder results from some obscure pathologic process the nature of which is not yet properly understood.

Terminations.—When fluid does accumulate in the bladder, Spicer finds that there are four possible terminations of the condition:

- (1) In the earliest stages, exstrophy of the bladder.
- (2) Urinary fistula at the umbilicus.
- (3) Distension and rupture of the bladder into the peritoneum.
- (4) Dilatation and hypertrophy of the bladder.

Obstetrical considerations.—The condition generally occurs in primigravidae and in the early child-bearing period. Multiparae of all degrees have also been affected. The labour is generally premature usually occurring between the 6th to 8th months of gestation. There is often an associated condition of oligohydramnios or hydramnios. In the majority of cases the presentation is vertex. The next most common is breech. But any presentation may occur, thus there are recorded cases of transverse, brow and face. Recurrence of the condition is rare.

Owing to the rarity of the condition the diagnosis is not generally made until the patient has been exhausted by prolonged labour and unsuccessful methods of delivery.

Treatment depends upon the degree of vesical distension. In minor degrees delivery is generally effected spontaneously or by simple traction on the presenting part. But if the enlargement is great then the foetal bladder must be perforated in order to effect delivery. According to Lynch (1906), the girth of the foetal abdomen which causes dystocia is usually 45 centimetres or more. It is interesting to note that dystocia has been observed only in half of the recorded cases (Dorland).

Rupture of the uterus has been noted on a few occasions.

Summary

(1) A case of congenital dilatation of the foetal urinary bladder is reported.

(2) The mother was an elderly primipara. Labour was premature but normal and natural. It was a case of twin pregnancy, one child being normal, and the other an anencephalic monster with the following peculiarities:—(a) Pseudo-hermaphroditismus-femininus, (b) absence of breasts, (c) dilatation of the bladder, (d) absence of the urethra, (e) presence of one kidney with two ureters opening into it, and (f) absence of the anus.

(3) The effect on labour in these cases depends upon the degree of distension of the bladder, dystocia arising only in case of enormous distension. There was no dystocia in the case reported.

SOME NOTES ON PLANOCAIN IN SPINAL ANALGESIA*

By J. FLETCHER ROBINSON, B.A., M.D.
F.A.C.S., F.R.C.S.E.

and

T. SESHACHALAM, L.R.C.P. (Lond.), M.R.C.S. (Eng.)
(Mysore University Medical College Hospital)

DURING the last nine months, we have used planocain with unqualified success in about 600 cases. Planocain is put up by May and Baker and is very efficient for local and spinal anaesthesia in 1 per cent solution. The solution

* Paper read before the Mysore Medical Conference held in February 1933.

is prepared in double-distilled water; this is boiled, planocain added, and the water boiled again. A fresh solution is prepared for each day's work. The solution is lighter than the cerebro-spinal fluid. The specific gravity of these two fluids has been estimated, all determinations having been done at 27 degrees Centigrade. After three hours standing, the specific gravity of the cerebro-spinal fluid was 1,007 and that of planocain—1 per cent solution—1,001.

As soon as it is injected, the planocain solution diffuses throughout the spinal fluid. In three to five minutes the drug is fixed in the sensory nerves and complete anaesthesia and relaxation are obtained.

Pre-operative preparation

The patient is not usually starved, but is given his usual meals on the previous day. No preliminary purgatives are given. Sodium bicarbonate in drachm doses, given three or four times a day for three days, maintains the alkalinity of the blood. Tincture of digitalis (minims xxx), given the previous night and repeated early the next morning, protects the heart. Three grains of luminol by mouth given an hour before the operation keeps the patient drowsy during the operation.

Level of injection

The injection is made between the spinous processes of the third and fourth lumbar vertebrae for all except upper abdominal cases, when the injection is between the second and third lumbar spines. We do not inject higher for fear of injuring the spinal cord, though Janeseo and others have injected even between the cervical vertebrae.

Position of patient

The injection is made with the patient sitting. The position of the patient after the injection depends upon the height of anaesthesia required. For all operations below the umbilicus the patient lies flat on the table for three minutes and then the table is lowered to Trendelenberg's position. For all operations above the umbilicus, the patient is placed on the back and the table lowered immediately to the Trendelenberg position. In three minutes, the anaesthesia is complete.

Dosage

The dosage depends upon the site of operation, the expected duration of the operation and the size of the patient. By experience, we have found the following doses to give satisfactory analgesia :

- For all operations below the symphysis pubis, 4 to 5 cubic centimetres,
- for all operations below the umbilicus, 5 to 7 cubic centimetres,
- for all operations between the umbilicus and ensiform cartilage, 7 to 12 cubic centimetres, and

for those above the ensiform cartilage, 15.25 cubic centimetres.

The anaesthesia lasts for about ninety minutes. In cases where the operations are expected to be prolonged, the dosage is increased proportionately.

The advantages claimed for this solution are its cheapness, ease of handling, the few complications that have followed and the unqualified success in anaesthesia obtained in every one of our cases. Planocain is very much cheaper than novocain. The preparation is easy. The complications during and after operations have been few. Of all the drugs used by us, this has given us the best results. We have not had a single case of failure in anaesthesia. With the drug in 1 per cent strength, 4 cubic centimetres is the minimum and 20 cubic centimetres the maximum dose we have given. Two radical mastoid operations have been done using 20 cubic centimetres of the solution and placing the patient in an extreme Trendelenberg position. The quantity of planocain in these two doses is 3 grains and $3\frac{1}{5}$ of a grain respectively and this small dose is not likely to give rise to toxic symptoms.

COMPLICATIONS:

On the table

Fall of blood pressure is one of the dreaded accidents on the table and was a common experience with us before we started planocain. This fall has been combated by a preliminary intramuscular injection of 10 minims of adrenalin, or 1 cubic centimetre of ephedrine solution a few minutes before spinal puncture. These doses may be repeated during the operation, if necessary. Fortunately, 1 per cent planocain and the regulated dosages now used have made this complication very infrequent.

Respiratory failure.—This happens when large quantities are used for higher centres. The solution reaches the fourth cervical segment and paralyses the diaphragm temporarily and the patient does not breathe, although the blood pressure and the heart beats are normal. This is only temporary, but has to be watched. The patient is told to try to take long, deep breaths, he is aroused by being spoken to frequently, and in a few minutes the effect on the phrenic nerve passes off and normal respiration is re-established. If paralysis persists, a mixture of 7 per cent of carbon dioxide and 93 per cent oxygen is given by the closed method and this starts the respirations. In one of our cases we had to resort to artificial respiration with oxygen for about ten minutes before automatic respirations started.

Other complications are nausea, vomiting (particularly in upper abdominal cases), pallor, perspiration, nervous excitement and a feeling

of tightness in the chest; these are all temporary and are combated easily.

After operation

Headache.—This is a distressing symptom and may be transitory or may continue for even three or four days. The headache varies in different cases and is seen more commonly among nervous patients, particularly those of the educated class, but less often amongst the uneducated, but more hardy, ryot. This headache is supposed to be due to low cerebro-spinal pressure caused by leakage through the puncture in the theca. This low pressure removes the cushion-like support from the base of the brain, which in turn presses upon the basal veins resulting in anæmia of the brain causing headache. To combat headache, we carry out the following treatment in all cases of lumbar anæsthesia, the moment headache is complained of: We raise the foot of the bed 10 or 12 inches thus attempting to keep the lower end of the spinal canal empty to prevent further leakage. Intramuscular injection of adrenalin chloride, 10 minims, is also useful. Pyramidon in 10-grain doses, repeated in six hours, if necessary, relieves headache in many cases. In

one case, a second lumbar puncture gave instantaneous and permanent relief.

Temperature and rigor.—In some cases there are rigor and rise of temperature. This comes on two to six hours after the operation and the temperature drops abruptly in a few hours.

Acute dilatation of the stomach.—This sometimes occurs a day or two after the operation and it has given us more anxiety than any other symptom. The treatment consists in recognizing the condition and instituting immediate treatment. The patient becomes restless, with very feeble and frequent pulse, and pallor and distension of the upper abdomen with respiratory distress sometimes accompanied by vomiting of slightly greenish fluid. Treatment consists in passing a small-calibre stomach tube through the nostril, emptying the stomach of all its contents, gently washing with saline, and leaving the tube in place for drainage until the tonic of the stomach returns. The prone position is essential in all cases. One cubic centimetre of pituitrin given intramuscularly every three hours is a great aid. Rectal and intravenous salines are helpful in restoring fluid loss if much vomiting has occurred.

A Mirror of Hospital Practice

A CASE OF ENDOCARDITIS TREATED WITH POLYVALENT ANTISTREPTOCOCCUS SERUM

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

R. CHOUDHURY, M.B.

and

B. SEN, B.Sc., M.B.

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

S. D., a Hindu female aged 25 years, was admitted under the senior author (R. N. C.) into the Carmichael Hospital for Tropical Diseases on 12th April, 1933, suffering from intermittent fever of a hectic type.

History of present illness.—The patient had a sudden attack of fever about 3 months before admission and had been getting it ever since. For the first month fever used to come every second or third day, but later it came on daily. During the second month she had suffered from alternating pains in different joints. There was no swelling of any joint and the pains subsided spontaneously. During the early part of the third month, she developed a rash on the body, which however subsided, but the fever continued as usual. She was treated outside the hospital for malaria, tuberculosis and 'B. coli infection' by different medical practitioners, but the fever could not be controlled.

The patient had previously always possessed good health. She has had 3 children one of whom is dead.

Condition on admission.—The patient looked ill and had an anxious expression. She was anæmic with a yellowish tinge of the skin. There was a daily rise of temperature to 103° or 104°F. with a chilly sensation but no rigor.

Physical examination revealed the apex of the heart in the 5th left intercostal space in the midclavicular line. There was no thrill but a soft systolic murmur was heard localized at the mitral area. Heart beats were irregular there being definite missing of beats at long intervals, showing partial heart block. The pulse rate varied from 60 to 80 per minute; pulse compressible, volume fair. Blood pressure was s/d -85/40 mm. of Hg. There was no cyanosis, dyspnoea, venous engorgement, œdema or petechial hæmorrhages. The lungs were clear, the abdomen soft and the liver and the spleen were not enlarged. Knee-jerks were normal and there was no urinary trouble. An examination *per vaginam* showed no pelvic abnormality.

Laboratory findings.—Blood—hæmoglobin 70 per cent, red blood cells—4,120,000, white blood cells—15,000. Differential count—polymorphonuclears—72 per cent, small mononuclears—21 per cent, large mononuclears—2 per cent, and eosinophiles—5 per cent.

No malarial parasites were found in the peripheral blood and blood culture for malaria was negative. The blood culture for bacteria was negative after 72 hours on two occasions. Wassermann reaction, Widal, Aldehyde and Antimony tests were all negative. Agglutination against *M. melitensis* was negative. Blood calcium and blood sugar were normal.

Urine.—There was no abnormality in the urine. A culture from a catheter specimen showed staphylococcus albus only.

Stools.—No ova or protozoa found; culture showed *B. pyocyaneus*.

Throat.—No hæmolytic streptococci found.

Electrocardiogram reports.—As the cardiac condition of the patient was peculiar electrocardiograms were taken at intervals. The results are given below:—

15th April, 1933.—P—R interval of 0.16 secs. which is probably a little high for Indians. T wave inverted. Slow heart rate possibly due to vagotonic action and myocardial degeneration.

24th April, 1933.—P—R interval 0.18 secs.; T wave flat but not inverted showing slight improvement in myocardial condition. Missing of heart beats clearly shown.

5th May, 1933.—P—R interval 0.18 secs.; heart rate 75 per minute. P wave normal size and contour. T wave upright, normal contour. Condition of myocardium shows improvement.

29th May, 1933.—P—R interval 0.18 secs. normal; P wave normal. T wave flat in lead II; R bifurcated in lead III. Indication—myocardial degeneration.

Treatment.—To start with, the patient was ordered absolute rest in bed and no medicine was given except a diaphoretic mixture, while preliminary investigations were being carried out.

After 4 days the pulse was observed to be getting slower and more intermittent. The patient was considered to be suffering from rheumatic endocarditis of a subacute type with partial heart block. She was put on sodium salicylate 15 grains 3 times daily but there was no effect on the temperature or pulse with this treatment after 7 days. Larger doses could not be given as the patient used to sweat profusely and feel depressed after administration of salicylate.

She was put on potassium iodide and liquor hydrargyrum perchloridum mixture which was continued for one week. For three days after this mixture was started there was no fever but the pulse remained about 60 and occasionally intermittent; the systolic bruit continued. On the fourth day she had fever again. For the next 3 days again there was fever, the condition of the pulse remaining unchanged. This was followed by a sudden sharp rise of temperature to 105°F. with a pulse rate of 68 per minute and the patient had to be given sponging and an iced saline per rectum. The iodide mixture was omitted and sodium salicylate gr. xv t.d.s. was started again. Next morning the temperature came down and the patient was in a collapsed condition; she was cold and clammy, temperature 96°F., pulse 50, respirations 24. She looked dazed and toxic, she was kept warm and stimulants were given. At this stage the patient started getting fits of unconsciousness resembling Stokes-Adam's Syndrome. As all the other treatments had failed she was given an injection of 10 c.cm. of polyvalent antistreptococcus serum intramuscularly. This improved her condition and the injections were repeated every other day till 60 c.cm. of the serum were given.

The temperature has remained normal since that time and the patient has felt better and has steadily improved. The pulse has also become quite normal in rhythm and is no longer intermittent. Later she was given hæmatinic treatment and after a prolonged rest in bed was allowed graduated exercises. She was discharged later.

Condition on discharge from the hospital.—Hæmoglobin 80 per cent, pulse 80 per minute, regular. Temperature normal. No symptoms. Apex of the heart—normal position, though a faint systolic murmur can still be heard. Skiagram showed no enlargement of the heart.

Remarks

1. The case was clinically one of carditis involving both myocardium and endocardium, chiefly the latter with partial heart block.
2. Although streptococci were possibly the cause, the septic focus being probably in the heart, they could not be isolated from the blood, throat, urine or elsewhere.
3. The treatment with sodium salicylate, atropine and potassium iodide appeared to do little good. The condition of the patient however started to improve rapidly after injections of polyvalent antistreptococcus serum. There was no rise of temperature after the first

injection. Whether the serum acted in a specific or non-specific manner is difficult to say.

A CASE OF HICCUGH CURED WITH APOMORPHINE HYDROCHLORIDE

By K. N. DUTT, L.S.M.F. (Punjab), L.O. (Madras)

*In-Charge Civil Dispensary, Bahadurgarh
Rohtak District, Punjab*

THE patient, a school inspector, consulted me with the complaint that he had been troubled with a hiccough for the past three days.

I gave him a hypodermic injection of apomorphine hydrochloride gr. 1/10 the same evening. Soon after the injection he felt slight giddiness and nausea. He fell asleep in an hour's time and awoke in the morning with his hiccough gone and apart from a few short attacks during this day he has had no further trouble.

A CALCULUS IN THE TONSIL

By S. C. SARKAR, M.B.

Assistant Surgeon, Walsh Hospital, Serampur

A MAN, aged about 45, came to the hospital for the removal of a fish-bone from his throat. I introduced my finger and felt something hard in the tonsil but could not detect any fish-bone. I then introduced a pair of crocodile forceps, guiding them by my finger which I kept in position. I found a rent in the tonsil and that a foreign body was lodged inside this hole. I grasped one edge of the rent with a toothed forceps and tried to remove the foreign body. After several efforts I was successful and I found that it was a calculus about the size of a big pea, black in colour and very hard. The man was completely relieved after the operation.

Calculi in the salivary glands and ducts are fairly common but I can find no record of one being formed in the tonsil.

INSANITY TREATED BY SULPHUR INJECTION

By K. K. SEN, L.M.P.

Narhan, Darbhanga District

History.—A Hindu male, 25 years of age, suffering from insanity of manic-depressive type, was brought for treatment a few months after the onset of the disease.

The attack was reported to be the second one, the first having taken place about two years previously, and it only lasted for a short time.

There was no history of venereal disease or addiction to any intoxicants. There was no family history of insanity.

Physical examination did not reveal anything particular excepting that the patient was debilitated.

Treatment.—'Sulfosin-leo'—prepared freshly by rubbing 1 per cent sulphur sublimate in pure olive oil and dissolving it at a temperature of 100°C.—was injected deeply on the outer side of the thigh at the junction of the upper and middle thirds, according to the recommendation of Major J. E. Dhunjibhoy, I.M.S.

Dosage.—The first dose was 1 c.cm. and the drug was injected bi-weekly the dose being increased by 1 c.cm. at each injection.

The maximum dose injected, however, did not exceed 4 c.cm. as that amount was sufficient to produce the desired pyrexia.

General treatment.—Fresh and nourishing food, baths, fresh air, occasional injections of hyoscine gr. 1/100 with morphine gr. 1/4 and atropine gr. 1/100.

Progress.—The temperature used to rise to 102°F. to 104°F. within twenty-four hours of each injection.

Pain was severe at the sites of injections. Altogether six injections were given the maximum dose being 4 c.cm. and the man completely recovered.

A PENETRATING WOUND OF THE ANUS

By M. K. PILLAI, B.A., M.B., C.M. (Mad.)
Civil Surgeon, Maubin, Lower Burma

History.—Maung Hla Gyaw, a Burman male, was admitted into the Civil Hospital, Maubin, Lower Burma, on the 25th December, 1932, with a long piece of lacerated small intestine and omentum protruding through the anus, as a result of a fall earlier the same day from a paddy heap 14 feet high on to a forked stick, the kind used to support country carts.

Condition on admission.—Temperature 100°F., pulse 94 per minute. No flatus or motions passed since the accident. The wound involved the anus and surrounding skin. Two loops of the small intestine each about 1½ feet long, with a piece of omentum about 1½ feet long, were protruding through the wound and lying loose over the perineum. The gut was lacerated, gangrenous and offensive. On examination by the fingers, a gaping wound was felt on the right side of the rectum, extending into the abdominal cavity. The abdomen was tympanitic and tender. The patient was restless, and had a feeble pulse and all the symptoms of peritonitis.

Operation.—Under chloroform, the parts were thoroughly cleaned, the omentum excised, the gangrenous portions of the gut to a length of about 3 feet excised and an end to end anastomosis made. The sutured gut, with the omental stump, was then gently returned into the abdominal cavity and the wound packed with iodine gauze. The patient stood the operation well.

27th December.—

Morning

Temperature—subnormal 97°F., pulse 94 per minute.

Evening

Temperature—101.2°F., pulse 112 per minute.

Patient restless and thirsty.

Turpentine stupes to abdomen, pituitrin injections and glucose water to sip, were ordered. Wound cleaned and another plug put in.

28th December.—

Morning

Temperature 98°F., pulse 80.

Evening

Temperature 100°F., pulse 100.

Passed flatus during the night and at time of dressing. Patient quiet, abdomen less tender. Wound clean and healthy, but bled a little. Same treatment continued.

29th December.—

Morning

Temperature—96.4°F., pulse 78.

Evening

Temperature—99°F., pulse 98.

Passed flatus frequently, had one loose, yellow motion, free from blood. Tympanites less, abdomen slightly tender. Treatment same.

30th December.—

Morning

Temperature—96.8°F., pulse 98.

Evening

Temperature—99°F., pulse 98.

Passed 5 more small liquid motions—abdomen soft and not tender. The wound is healing, the rent in the rectal wall closing up. Patient complaining of hunger, but still fed on glucose water only.

1st January.—Temperature—normal morning and evening. Bowels open.

3rd.—Patient complains of hunger and weakness. Two cups of Horlick's milk given in addition to the glucose water.

6th.—Two cups of Horlick and one cup of cow's milk given. Slight discomfort after cow's milk, but relieved after a good normal motion.

9th.—Wound healing satisfactorily—abdomen quite soft and normal. Patient put on milk and rice conjee.

12th.—Slight discomfort after rice conjee, as the bowels were not quite free.

15th.—Bowels loose. Patient not strong—same diet with some stimulants.

19th.—Patient gaining strength, but bowels inclined to be constipated, relieved by liquid paraffin.

From this time he steadily improved and put on weight. The wound healed. He was put on ordinary diet, and discharged from hospital on 10th February, 1933.

The case is peculiar as the gut and omentum protruded through the anus, the anastomosis was done *in situ* and the gut pushed back into the abdominal cavity through the anus.

RECURRENT VOLVULUS OF THE SIGMOID COLON CURED BY COMPLETE SIGMOIDECTOMY

By F. C. FRASER

LIEUTENANT-COLONEL, I.M.S.

District Medical Officer, Coimbatore

THE patient, a man of some fifty-five years of age, was admitted in the month of March for volvulus of the sigmoid colon. Abdominal section was performed by Lieut.-Col. Paton, I.M.S., and the volvulus reduced.

The patient was re-admitted again in the following October with a recurrence of the old trouble. Abdominal section was performed by myself and the volvulus again reduced. To prevent a recurrence of the twisting, the colon was stitched to the abdominal parietics. It was greatly hypertrophied and harboured a mass of constipated faeces which probably caused the volvulus. The patient gave a history of long continued obstinate constipation.

He returned again in the following March when I performed abdominal section for the third time within a year. The parietal adhesions had stretched the stitching having quite failed to do its work, so I decided the only procedure to carry out was to remove the whole of the sigmoid loop. This was done and owing to the enormous hypertrophy of the loop, an easy end-to-end anastomosis was performed. Six hours after the operation the patient started a profuse diarrhoea probably due to catarrh from retained decomposing faeces. In spite of this dangerous symptom, he showed no other disturbance and left the hospital two weeks later completely healed.

PERSISTENT LEFT SUPERIOR VENA CAVA

By T. SESHACHALAM, L.R.C.P. (Lond.), M.R.C.S. (Eng.)

Professor of Anatomy, University Medical College, Mysore

and

R. NAGENDRAN, M.B., B.S.

Lecturer in Anatomy, University Medical College, Mysore

THE persistence of two superior venae cavae is a rare occurrence.

The body of a male aged 35 (past history not known), dissected in the anatomical department of the Mysore University Medical College, presented a left superior vena cava in addition to the right. The left superior vena cava, formed by the union of the left internal jugular

with the left subclavian vein, descends vertically to the left of the arch of the aorta crossing the root of the left lung in front. It then turns to the right lying in the groove on the

condition described above, the transverse communicating branch is small, and the left primitive jugular and left duct of Cuvier have persisted and form the left superior vena cava.

Anterior view.

posterior aspect of the heart which is normally occupied by the great cardiac vein and opens into the right auricle independently. The right superior vena cava is formed normally and opens independently into the right auricle but is smaller in calibre. The left innominate vein which is represented by a small communicating vein between the two venæ cavæ receives the inferior thyroid veins.

In addition to its main tributaries the left superior vena cava receives the following veins :—

- (1) The left superior intercostal vein which receives a communication from the hemiazygos vein.
- (2) The thoracic duct.
- (3) The left internal mammary vein.

Embryological explanation

The right and left ducts of Cuvier receive the corresponding primitive jugular and subclavian veins and form the right and left superior venæ cavæ of embryonic life. A transverse communication forms between the two primitive jugular veins which later enlarges and forms the left innominate vein. The portion of the left primitive jugular, below the transverse communicating branch, atrophies and forms the upper part of the left superior intercostal vein, and the left duct of Cuvier atrophies and is represented by the vestigial fold of Marshall. In the abnormal

Posterior view.

Indian Medical Gazette

SEPTEMBER

CHOLERA AND BENGAL

ATTEMPTS are frequently made to estimate the amount in millions, or more often billions, of pounds that the existence of some particular disease costs the world. These estimates, which are seldom built on a very sound basis and are claimed only as the roughest of approximations at the best, are designed to impress hard-headed and hard-hearted business men to whom an appeal in the terms of the sufferings of human beings would mean nothing, and they probably serve their purpose, for even if the business man is inclined to accept them with reservation, knowing the methods by which they were made, they usually find favour with the politician—if they suit his purpose—and they certainly impress the readers of the headlines of the daily papers. Cholera in particular lends itself to this form of appraisal, as the dramatic rapidity of the course of the disease, which leaves little time for the victim to suffer, the high mortality, and the infrequency of any morbid scarring in those that recover, reduce the human suffering in connection with this disease to personal bereavement and to such conditions as are the direct outcome of economic loss if the victim happens to be the breadwinner of the household.

As far as the world in general is concerned the economic loss that is caused annually by the deaths of the tens of thousands of workers is unimportant in comparison to the enormous expenditure that is incurred on the organization for the prevention of the spreading of this disease. Port-health authorities in all parts of the world are continually kept on the alert to prevent the entry of the disease into their countries; and in the countries into which, despite this vigilance, it does find its way now and then, the public-health authorities have to maintain continuously a special organization for dealing with it. In every province in India the prevention and treatment of cholera is one of the most important functions of the public-health departments. Thus the expenditure that is incurred on account of the existence of this disease is distributed, practically speaking, over the whole world.

Now Bengal is held by the outside world to be the home of all cholera, and though there are undoubtedly other endemic foci in the world, the position of India both commercially and geographically makes this opinion regarding the responsibility of India in general and Bengal in particular in the matter of world cholera, virtually, if not actually, true. It is therefore

not surprising that everybody looks to India to do something towards ridding the world of this very expensive incubus. On the other hand it cannot be said that India has failed to realize her responsibility in this matter: every effort is made at India's ports to detect infected persons and to prevent them from leaving the country, whereas within the country itself the health departments of every province are continuously on the lookout for the first signs of the epidemic incidence of the disease; they have permanent organizations for actively combating it, and they take the most elaborate—and in recent years most successful—precautions to control the disease during *melas* and festivals, which in previous years were always the starting points of epidemics. Extensive studies into the epidemiology of the disease have been carried out by Russell, Rogers and Gill. Cholera has for years been high up on the list of diseases on which research is being conducted, and it was only the unfortunate financial crisis that prevented a large commission from being formed under the auspices of the Indian Research Fund Association to carry out a very complete investigation into this disease in all its aspects. That this commission never came into being and that its director-designate, Colonel F. P. Mackie, was allowed to retire and was thus lost to India was perhaps one of the most unfortunate sequelæ to the falling of the axe on the research organization in India.

There are at present four major enquiries being conducted on the subject of cholera in India, namely,

(a) a basic enquiry on the cholera vibrio, on its virulence, and on the virulence of the cholera-like vibrios under the Endowment Fund of the Calcutta School of Tropical Medicine and the Indian Research Fund Association.

(b) an enquiry into the antigenic structure of the cholera vibrio under the Indian Research Fund Association at the All-India Institute of Hygiene and Public Health, Calcutta.

(c) a bacteriophage enquiry under the Indian Research Fund Association at Patna.

(d) a bacteriophage enquiry in Shillong, also under the Indian Research Fund Association, combined with a field enquiry in Assam.

There is also an enquiry at the King Institute, Madras, and another in connection with the epidemiological bureau at Lahore. It can thus be said that India as a whole is not neglecting her duties in this matter, but is making a serious attempt to deal with the cholera problem.

If the world looks to India to do something about cholera, other provinces in India might very well turn to Bengal and ask what she, the cause of all the trouble, is doing about it. Bengal has a well-organized public-health department which has always made anti-cholera work one of her main activities; this department has a vaccine factory, makes and issues large quantities of vaccine, and each year carries out between one million and one million

and a half inoculations. Special arrangements are made for maintaining sanitary conditions at *melas* held within the province, and for pilgrim traffic, but the activities of the departments financed by the Bengal Government are directed mainly at holding in check the disease within the province and preventing its spreading beyond our borders. Were we to point the accusing finger at the Bengal Health Department and say 'How is it that during last quarter 40 per cent of the cholera deaths in India occurred in this province?', their answer would be simple; they would say 'Other provinces have only to prevent the entry of cholera, whereas we have it continually in our midst and every tank in Bengal is a potential source of infection'. This brings us to our point; all the measures that we have recounted above are merely palliative, but is Bengal doing anything to locate and to attack this source of the cholera of the whole world which lies somewhere within the province? There is at present research being done on cholera in Calcutta, but these researches are not sponsored by the Bengal Government. Bengal is a poor country, it may be said, it is no fault of her own that she is blessed with this unfortunate heritage which if it costs the world a great deal costs her more, she is finding it difficult enough to meet her actual financial obligations, and is not in a position to worry about problematical moral ones. But all activities are not necessarily expensive and Bengal could show India and the world that she is alive to her responsibilities in harbouring this undesirable inhabitant, by other means than by financing research workers.

It is suggested that a cholera committee should be formed in the province representing the Government executive, preventive medical organization, medical relief organization, and medical research. The committee should be of a semi-permanent nature, and it should be a small but strong one, so that though it did not possess executive powers there would be some chance of its recommendations being put into effect. Such a committee should collect the information that is available on the subject from various sources in the province, examine the results achieved by the various methods of cholera prevention at present in force, explore the possibilities of other methods which have been suggested by recent research work, and formulate a policy which would have as its final objective the banishing from the province of a preventable disease that has been endemic for more than twenty-five centuries.

The present methods of cholera prevention that are commonly employed are :—

Isolation.—This to be effective means the provision of suitable quarters and legislation to enforce their use. There is no doubt that the provision of hospital accommodation for cholera cases in the large towns in Bengal is a matter that admits of considerable improvement, but

isolation will never be applied satisfactorily in the rural areas and can therefore not be considered as a measure that is likely to achieve much by way of stamping out the disease.

Sterilization of water.—There is overwhelming evidence that cholera is mainly a water-borne disease and that wherever a wholesome water supply has been provided the disease has come to an end. It will be many generations before this can be achieved throughout the villages of Bengal, but it may be the eventual solution of the problem. However, spasmodic attempts at sterilization, such as the addition of potassium permanganate and chlorinated lime to wells and tanks, methods practised at present, are both costly and ineffective.

Preventive inoculation.—Anti-cholera vaccination has been employed for a number of years both in India and other parts of the world without any marked diminution in the incidence of the disease. It is important, therefore, that a proper assessment be made of its value in terms of incidence or mortality amongst the vaccinated population as compared with the unvaccinated, taking into account all the factors, whether environmental or the natural variations of the disease, which may influence such assessment. Before the efficacy of vaccination of man against cholera can be judged the following problems in active immunization must first be solved :—

(a) The danger, if any, of overlapping of inoculation and exposure to infection. This must be controlled by laboratory data.

(b) The assessment of the relative merits of the various types of vaccines in popular use and the mean duration of immunity conferred by different methods of protective vaccination.

(c) The value of active immunization in the light of recently acquired knowledge of bacterial antigens. The nature of bacterial antigen is one of the most important recent contributions to the science of active immunization and shows the necessity for a very close co-operation between the research laboratories and those engaged in the preparation of vaccines. It has been established that vibrios may so change in their antigenic properties (R and S; H and O variants) that they may become entirely without any protective value in immunization.

At the present moment a cholera vaccine is just a vaccine made from some strain or strains of cholera vibrios; the question whether it is made from a Bombay strain of cholera, prepared in France, and used in Calcutta, or whether it is prepared in Calcutta from strains that were isolated years ago and have been subcultivated under a variety of conditions ever since, does not appear to be considered.

Authoritative statements based on controlled field experiments together with laboratory controls on these points are necessary before the value of cholera vaccines at present in use can be judged.

Vaccination by bacteriophage lysates of vibrios, and other methods of inoculation might be considered; for example, the few animal and human experiments in the use of bacteriophage lysates of bacteria that have been reported have shown that there is a more rapid and a more solid development of immunity response with these lysates than with the ordinary types of vaccines. This is a method of immunization which owing to its simplicity and reputed efficacy deserves a trial.

Bacteriophage prophylaxis.—Experiments with bacteriophage in the prevention of cholera have been carried out by different observers, by d'Herelle in the Punjab, by Asheshov at Puri and in Behar, and Morison in Assam; the results appear to be encouraging, although they do not all bear close mathematical examination. It is not, in our opinion, a method that can be altogether dismissed, and it might be given a controlled trial in a small village area.

There are of course many other aspects of the cholera problem, but we will content ourselves with mentioning these few. There is in existence much organization for dealing with cholera, both from the preventive and from the medical relief point of view, and there are many research workers in the field, so that most of these problems could be tackled without introducing more organization or more research workers, if a committee could be formed on the lines suggested above to correlate the work of these various departments.

Medical News

'THE PRESCRIBER'

We have before now drawn our readers' attention to this useful Journal. In the May number there is a very complete review of the latest developments in endocrinology. Dr. D. M. Tudor contributes a note on incipient hypothyroidism in which it is shown how closely associated this condition is with many symptoms usually attributed to other causes. The various glands are dealt with in a series of up-to-date reviews, prepared by some half-dozen collaborators, bringing the knowledge of the subject down to April of the present year. In the case of the adrenal cortex, for example, there are four pages devoted to recent advances, to the anterior pituitary about three pages, and to the female gonads four pages. The endocrine products of the new British Pharmacopoeia receive special attention, and this issue of 56 pages of text is a complete review of the knowledge of the subject at the moment.

FIFTY YEARS AGO

(From the *Indian Medical Gazette* of September, 1883, Vol. XVIII, pp. 257 and 258)

ACCORDING to the most recent telegrams, cholera appears to be abating in Egypt, and it does not seem as yet to have made its appearance in Europe. At the time the mail of 3rd August left England, the total mortality caused by the disease was estimated at 11,600; some 80 deaths had taken place among British troops, including three officers. Surgeon-General W. G. Hunter, the late head of the Bombay Medical Service, had been deputed to conduct inquiries regarding the origin and spread of the epidemic. He was accompanied

by a band of medical volunteers. A scientific mission has, at the suggestion of M. Pasteur, been sent from France. It consists of four young doctors skilled in microscopic investigations, Drs. Roux, Thuillier, Straus and Nocard, and the special object of the mission is to search for a microbe whose discovery Pasteur anticipates with confidence.

The following interesting facts are culled from the Government resolution on Dr. King's reports on Cinchona Cultivation and Alkaloid Extraction for the year 1882-83.

The total number of cinchona trees of all sorts at the close of the year was 4,711,168, namely red (*Cinchona succirubra*) 3,713,200, yellow (*Calsaya ledgeriana*) 662,998, hybrid unnamed variety 304,378, and other kinds 30,592.

It is satisfactory to observe that the crop of the year is the largest that has yet been harvested on the plantations. It amounted to 396,980 pounds of dry bark, of which 372,610 pounds were of *Succirubra*, 22,120 pounds of *Calsaya* and *Ledgeriana*, and 2,250 pounds of hybrid bark. By far the largest portion of the produce was made over to the factory for conversion into cinchona febrifuge, while about 41,800 pounds of yellow and red barks were sent at the request of the Secretary of State to London to be there converted into various forms of febrifuge and returned to this country for trials by the Medical Department.

Dr. King has eventually succeeded in obtaining an analysis of the bark renewed on *Succirubra* trees that had their original bark removed by the shaving process introduced by Mr. Moens, the distinguished Director of Cinchona Cultivation to the Dutch Government. The results are thus described by Dr. King: 'The bark renewed rather slowly, but the analysis shows that it is very rich both in quinine and cinchonidine; and there can be no doubt that in countries where red bark trees are perfectly at home, and where their continuance in good health and vigour for a long series of years can be absolutely counted on, this shaving process must be a very excellent one.'

The price of the febrifuge was Rs. 8-8 a pound, and the percentage of the alkaloids extracted from the bark used in manufacture 2.73. The issues amounted to 8,901 lbs. 4 ozs. The issues to the public were 120 lbs. below those of 1881-82.

Current Topics

Atebrin in the Treatment of Malaria in Malaya

By SURGN. LIEUT.-COMMANDR. DAVID DUNCAN, M.B., CH.B., D.P.H., R.N.

(Abstracted from *The Malayan Medical Journal*, Vol. VIII, No. 2, June, 1933, p. 79)

SUMMARY AND CONCLUSIONS

THE medical organization at H. M. Naval Base, Singapore, is such that all Asiatics, whether employed directly by the Admiralty, or by the main contractors, or sub-contractors, are under strict medical control. They are medically examined on entry and during their sojourn on the Base a detailed history of each man is kept, all illness and treatment are recorded, and cases can readily be followed up after discharge from hospital.

During the past 15 months the writer has treated over 4,000 cases of malaria. Atebrin has been used for a period just over six months and over 400 cases have been treated with this drug.

Observations on the result of quinine treatment are made, and they correspond more or less to the general findings of workers who have used this drug in the treatment of malaria.

Atebrin is easily administered either in tablet, powder or liquid form. It leaves no lasting bitter taste in the mouth, and is therefore readily administered to children. It causes no deafness, ringing of the ears, photosensitivity, giddiness, anorexia, nausea, gastric upset, albuminuria, nor general depression. Cases under treatment in hospital are bright and cheerful. Patients are discharged to duty fit, and have not that lowered vitality which in the case of quinine treatment probably accounts in some degree for the frequency of relapses.

The fluorescent test for excretion of atebrin in the urine, faeces, and milk is not a satisfactory one unless the amount of atebrin being excreted is considerable. Atebrin is excreted in sufficient quantity in the urine to give a positive fluorescent test for from three to six days after treatment has ceased.

The optimum adult dose is 0.1 gramme or 1½ grains given three times a day for five days. Children even infants bear atebrin well, and to obtain good results the full dose suggested must be given.

Fifteen Asiatic women and forty-two Asiatic children were treated as outdoor patients. Atebrin was administered in full doses at various stages of pregnancy and no adverse effects were noted. Atebrin was administered to nursing mothers; it was found to be excreted in the mother's milk, and in one case was demonstrated in the infant's urine. None of the babies concerned showed any ill effects. Notes are given of a family of six children which were infected with benign tertian malaria which resisted all forms of treatment with quinine. Atebrin appears to have been somewhat more successful although it is too early yet to state whether the parasites have been finally eradicated.

The increase in the percentage of hæmoglobin in the blood during the course of treatment is in part due to rest and nourishing food. The persistence of the higher hæmoglobin index is noteworthy and satisfactory.

In benign tertian infections all parasites disappeared from the peripheral blood after 0.8 grammes of atebrin had been given over a period of two and a half days. In subtertian infection all asexual parasites disappeared from the peripheral blood after 1.0 gramme had been administered over a period of three days. There is a possibility that atebrin may have some delayed action on sexual forms as they were noted to disappear four or five days after treatment had ceased. Plasmoquin however gives more certain and quicker eradication.

In 93 per cent of benign tertian cases the temperature had dropped to normal within 44 hours and there was no subsequent rise. In subtertian infections the temperature dropped to normal in from 48 to 56 hours after the commencement of treatment. There was no difference noted in the temperature charts whether the case was treated with atebrin alone or in conjunction with plasmoquin.

The immediate effect on enlarged spleens during treatment was favourable. After an interval of some months 77.4 per cent of cases with splenic enlargement showed a marked decrease in the size of the spleen. This was also marked in the larger spleens.

Benign tertian cases treated with atebrin alone showed a relapse rate of 10.7 per cent. Benign tertian cases treated with atebrin given in conjunction with plasmoquin showed a relapse rate of only 5 per cent. It is doubtful whether in order to obtain this lower relapse rate one is justified in giving plasmoquin along with the atebrin in all benign cases. Subtertian cases treated with atebrin and plasmoquin gave a relapse rate of 3 per cent.

No toxic symptoms which could be attributed to the taking of atebrin have been noted. Discoloration of the skin has been seen in several cases. In no case where atebrin has been given alone have any abdominal symptoms been noted.

A general remark is made on the probable dangers of plasmoquin and of the necessity of exercising the greatest care when administering this drug.

Atebrin is a considerably cheaper method of treatment than quinine, from the view-point of the price of the drug, the saving in hospital costs and reduction in the time lost by the patient.

Undulant Fever

(Abstracted from the *Prescriber*, Vol. XXVII, June, 1933, No. 6, p. 217)

History.—The conditions known as undulant fever, abortus infection, and Malta or Mediterranean fever, while differing somewhat in character, appear to be varieties of the same infection, caused by different strains of the same organism.

For many years an infection of cattle, causing epidemic abortion in the animals, has been recognized. The causative organism was isolated by Bang in 1897 and named by him *Bacillus abortus*.

About forty years ago much trouble was caused in Malta by the prevalence of a certain kind of fever among the troops and the civilian population. This particular disease—first recognized during the Crimean War and known as Mediterranean or Malta fever—was found to be caused by an organism isolated by Bruce in 1887 and termed by him *Micrococcus melitensis*. In 1904 a British Commission investigated the causes of Malta fever and traced its origin to goats, whose milk was being largely consumed by the troops on the island. Removal of the goats and stoppage of the consumption of their milk completely stamped out the disease among the troops and greatly diminished its incidence among the civilian population.

Later it was observed that the incidence of Malta fever in goats was accompanied by frequent abortion among the animals, and in 1918 a certain similarity was shown to exist between *Bacillus abortus* and *Micrococcus melitensis*. A year or two later this similarity of the two organisms was confirmed, and in 1921 an important addition to knowledge of the subject was made when it was shown that *Bacillus abortus* may be present in the milk of cattle that have aborted, or even in that of carriers which have not aborted, and convey infection to human beings causing abortion in pregnant women.

In 1923 the identity of *Bacillus abortus* with the organism of Rhodesian undulant fever was established, and a year later it was shown definitely that the cow was the source of infection, and that in undulant fever the patient's serum was capable of agglutinating both organisms. Investigation soon revealed the existence in non-tropical countries of infection with *Bacillus abortus*, and while the symptoms did not in all respects tally with those of undulant fever as known in the tropics, the finding of the organism, and the application of agglutination tests, established the identity of the disease.

Bacteriology.—It is now generally held that *Micrococcus melitensis* is in reality a small bacillus and not a coccus, and the name adopted for it is *Brucella melitensis* (after its discoverer). The 'abortus' organism is regarded as a strain or variety—*Brucella melitensis* var. *abortus*.

Recent investigation has disclosed the existence of a number of varieties of *Brucella*. While these are usually referred to as if they were separate species, they are more correctly described as varieties or strains of the same organism. The more important of these are: *Brucella melitensis*, the caprine strain responsible for Mediterranean fever, *Brucella melitensis* var. *abortus* (bovine strain), and *Brucella melitensis* var. *suis* (porcine strain), these two being responsible for undulant fever. The porcine strain is much more pathogenic for man than the bovine strain; it seems to be more prevalent in America, while the bovine strain is more common in these islands. It is believed that cows may become infected with the porcine strain if

kept in proximity to swine. The various strains may to a certain extent be distinguished one from another by biochemical methods.

Etiology.—Infection by *Brucella abortus*, it appears, may reach the patient either by direct contact with animals harbouring the organisms—which seems to be common in America and on the continent of Europe—or by drinking the milk of infected cows, the more usual source of infection in Britain. It has been established that pasteurization of the milk completely destroys the organism and renders the milk safe for drinking. An investigation in Edinburgh only a year ago revealed the presence of *Brucella abortus* in about 35 per cent of samples of unpasteurized milk purchased in the ordinary way. In spite of this relatively wide distribution of the organism in milk, the actual number of cases recognized as undulant fever is comparatively small. This may be explained in two ways: first, many cases may be diagnosed as influenza and are not recognized as undulant fever; second, and more probable, individual susceptibility plays an important part and only a small proportion of these consuming abortus-infected milk are affected. The disease does not occur in epidemic outbursts among consumers of infected milk.

The portal of entry depends upon the manner of infection—in cases of contact with animals it may be through the skin, while with milk it is assumed that infection takes place through the alimentary tract. The tonsil has also been shown to be a possible route, and it has been suggested that the organism may settle and multiply there until the resistance of the host has been sufficiently lowered by fatigue or disease to permit its invasion into the blood-stream.

Symptoms.—Typical undulant fever is characterized by a series of febrile attacks, each lasting one or more weeks and subsiding into a period of absolute or relative apyrexia of uncertain duration. In his original description of Mediterranean fever, published in 1863, Marston remarked that no fever was so irregular as this in its course and symptoms. In the disease as it occurs in this country the type of chart varies, but the pronounced irregularities are characteristic. Sudden drops of temperature are accompanied by drenching sweats. In spite of the extreme irregularity of temperature, the characteristic evening rises followed by morning falls are usually seen. The duration of the disease is variable: it seldom lasts less than three weeks, more often six weeks or two months, and many cases are on record which lasted one or two years. The average severity of cases infected by *Brucella melitensis* is greater than that of abortus-infected cases.

Diagnosis.—As already mentioned, certain characteristic signs and symptoms are very helpful in diagnosis of undulant fever. The temperature chart is peculiar, the sudden drops of temperature are accompanied by heavy sweats, and the prostration of the patient is much less intense than would be expected from the temperature chart. Still the disease is liable to be mistaken for paratyphoid, influenza, etc., and diagnosis is often a matter of difficulty. For this reason laboratory diagnosis is of great importance, and in some cases is the only means of recognition. Several methods are available: (1) the agglutination test; (2) isolation of the organism from the blood or the excretions; (3) animal inoculation; (4) the intradermal test.

Agglutination test.—Without doubt the most valuable laboratory method of diagnosis is the agglutination reaction. This is usually given by the patient's serum after the second week of the disease, though sometimes it appears as early as the fifth day, and cases have been known in which the serum failed to agglutinate throughout the course of the disease. The test is performed by mixing graded quantities of the patient's serum with a killed suspension of *Brucella abortus*, incubating in a water-bath at 55°C. and reading the results after four and eighteen hours. The serum should be in various dilutions from 1:10 to 1:5,120.

Isolation of organism.—Cultivation of *Brucella abortus* from the blood or excretions is often possible, there being apparently a distinct relation between its presence in the blood and the patient's temperature—the higher the temperature the more probably will the organism be found.

Intradermal test.—Burnet's intradermal reaction consists in the injection into the skin of 0.5 c.cm. of a killed broth-culture ('melitene' or 'abortine') containing 500,000 organisms. A positive reaction is indicated by a red oedematous area at the site of injection, which persists for several days. Control injections are made in adjacent areas of skin. The test does not distinguish between the different varieties of *Brucella*, and for this reason the organism used is *Brucella abortus*. The method is simple, and frequently gives positive results where agglutination fails; on the other hand cases have been known to prove negative to the intradermal test where the agglutination titre was as high as 1:500. The test is not definitely specific, but is of value as a diagnostic in cases where no brucella agglutinins are present in the blood and when the organism cannot be grown on culture of the blood, urine, bile, or faeces.

Some American workers report a serological and clinical investigation of 100 persons exposed to infection through a known infected milk supply. Of these 22 showed evidence of active infection of the ambulatory subclinical type, 38 showed evidence of past infection, and 40 were not infected. None of the laboratory procedures employed was entirely specific; the intradermal test is regarded as being of distinct diagnostic aid. Laboratory findings, these workers conclude, are of extreme importance in the differential diagnosis of undulant fever.

Treatment.—At present no remedy is known to be specific for undulant fever, treatment being mainly symptomatic. Amidopyrine (B. P. 1932) has been found useful to combat headache and insomnia, while the pyrexia may be treated with antipyretics such as acetylsalicylic acid. In some cases intravenous injections of acriflavine (B. P. 1932) have proved of value, and several workers report good results from injections of S. U. P. 36. In America a vaccine has been placed on the market consisting of a saline suspension of killed organisms of *Brucella melitensis* var. *abortus* (bovine) and var. *suis* (porcine). Reports on its use are scanty, but on the whole they are favourable.

Zammit and Debono (Malta) report further developments in the preparation of a vaccine for the immunization of goats. Three years ago (*Prescriber*, 1930, Nov., 375) reference was made to their previous work when it was stated that while they had not achieved complete immunity they had succeeded in conferring a certain measure of protection in what is normally a very susceptible animal. They now say that they have elaborated a vaccine from a special avirulent strain of *Brucella abortus*, and that intradermal inoculation of goats with this vaccine is sufficient to protect them against the mild infection usual in these animals. These workers are confident that if the goats in Malta are treated as they suggest the spread of undulant fever might be effectually stopped.

A Note on the Uses of Glucose in General Practice

By F. O. TAYLOR, M.B., CH.B.

(From the *Practitioner*, Vol. CXXX, April, 1933, No. 4, p. 508)

THE general practitioner who has attended many families for some years knows from experience which of his young patients are prone to develop acidosis. As a rule they are of the nervous and delicate type, and readily go under to catarrhal infections. For some years, on the ground that alkali neutralizes acid, I tried to saturate these children's systems with bicarbonate of sodium, magnesium carbonate, and the like. But often vomiting was caused or increased; the temperature

remained high, the breath fruity; these symptoms show that, although there is not any demonstrable complication, the parents should be warned that some serious condition may be on the way. By slow stages, however, recovery would come, no doubt assisted to some extent by persistent alkaline medication. In passing, let me say that ammonium acetate has kept a high place in the purely medicinal treatment of juvenile sufferers from feverish complaints.

About eight years ago, after worrying for several days about the apparently serious condition of a child of 3 years of age who was maintaining a temperature of 102° to 104° F., without any obvious cause and with acidosis for which the usual alkaline treatment was given, I remembered that glucose was stated to be of value in such cases and promptly prescribed it. The temperature fell at once, and the child improved in an extraordinary way. Since then a load has been taken off my mind. If the acidosis is relieved but feverish malaise still persists, there must be some further complication.

Recently I attended a boy of 8 years with obvious acidosis. The administration of two heaped teaspoonfuls of medicinal glucose every two hours in water stopped his vomiting, cleared his urine, and removed the fruity odour from his breath, but did not bring down his temperature or stop some vague pain in the left upper epigastrium. I expected further developments. Eventually a basal pleurisy appeared.

Another small patient, always easy to treat for his chills and colds, one day did not respond to the usual measures; as a matter of fact he became seriously ill with only very vague abdominal pain. I sent the boy to hospital, where also he was treated as an obstinate case of acidosis; operation later revealed pneumococcal peritonitis.

Negative observations are as useful in some cases as positive findings; glucose cannot cure bacterial infections. As children grow, so does their liability to acidosis diminish. The adult simulates the condition with hyperacid urine and gastric secretion. But the fruity breath, in my experience, is usually associated with the acetonuria of diabetes, or with the terminal stages of dissolution.

As a valuable food, non-irritating, and easily absorbed, glucose is the only nutriment which I allow to adults during the rare cases of pneumonia I see nowadays. In hyperemesis gravidarum it can be freely used as a rectal meal with or without normal saline, and asthmatic children often derive great benefit from large quantities in addition to ordinary diet.

The Treatment of Acute Gonorrhœa in the Male

(Abstracted from the *Medical Journal of Australia*, Vol. I, No. 19, 13th May, 1933, p. 596)

ADVICE TO PATIENT

At the outset the patient should be warned as to the seriousness of his disease, that he must not give up treatment until assured of cure by his doctor. Half-hearted co-operation between practitioner and patient usually leads to bad results, and so as to insure the necessary co-operation, the patient should make frequent visits to the surgery. The patient should be particularly warned as to his mode of life; for any indiscretion during the course of the disease will most certainly delay cure. For example, any condition which tends to lower the resistance of the patient, such as keeping late hours, excessive smoking and indulgence in alcohol in any shape or form, cycling, riding on horse back, all forms of strenuous exercise are to be avoided, and sexual excitement must be debarred. No matter how good the local treatment, if the above-mentioned rules are not observed, results are indifferent, so that the patient's salvation lies largely in his own hands. Much has been written with regard to the prohibition of certain articles of diet, but experience has proved that

the ingestion of these foods has little or no effect on the course of the disease. The patient should be allowed good, wholesome food, including meat, otherwise his life will become a misery and thereby his natural resistance will suffer. He should be instructed to drink large quantities of water, which tend to correct the influence of irritating foods, and to micturate frequently, which serves the useful purpose of irrigating the urethra from behind. Attention should be paid to the bowels, and it is a good practice to order a good dose of opening medicine at the outset.

DRUG TREATMENT

No medicine as yet has been proved to be a specific for gonorrhœa, being merely prescribed for the alleviation of symptoms and sometimes as a placebo. For this purpose a simple mixture containing potassium citrate 1.2 grammes (20 grains) and potassium bicarbonate 1.0 gramme (15 grains) to 30 cubic centimetres (one fluid ounce) is useful, as is also a gelatine capsule containing sandalwood oil 0.6 mil (ten minims) and methylene blue 0.015 gramme (one-quarter of a grain), given three times daily. Particularly is this capsule useful in acute inflammation of the posterior urethra. Morphine 0.015 gramme (one-quarter of a grain), prescribed as a suppository, is sometimes necessary for the pain of acute inflammation of the posterior urethra.

VACCINES

Vaccines have largely fallen into disfavour in the treatment of acute uncomplicated cases of gonorrhœa, but have been universally used in cases with systemic involvement. Experiments carried out at the Rochester Row Military Hospital by Thompson and Lees in 1919 proved that, when large doses of detoxicated vaccine were used, gonococci disappeared from the discharge in less than half the number of days than in cases treated without vaccine. The administration of vaccine in acute gonorrhœa seems to be quite logical for the purpose of improving the patient's resistance. Detoxicated gonococcal vaccine is given intramuscularly into the upper and outer quadrant of the buttock in doses increasing from 2,500 millions to 10,000 millions, every fifth day.

LOCAL TREATMENT

The patient is instructed to procure a roll of cotton-wool, a packet of gauze, a tight suspensory bandage and also a small all-glass syringe with a blunt point. The wool is cut into squares and inserted on the inner surface of the suspensory bandage for the purpose of catching the discharge. Gonorrhœa bags and plugs of cotton-wool are not to be used, nor is anything to be tied around the penis, for by so doing drainage is interfered with. In patients with long prepuce a strip of gauze is placed over the glans penis and then the prepuce is pulled forwards. This dressing prevents the discharge from accumulating in the sulcus, thereby causing an infection of Tyson's glands, which are situated one on either side of the frenum.

The two methods of choice for local treatment are: (a) irrigation from douche can, (b) injection by small all-glass syringe. Most experts prefer the large syringe of 150 cubic centimetres capacity for irrigating purposes, but unless the operator is thoroughly practised in the technique of its use, more harm will be done than good. In general practice, therefore, the douche can method with special irrigating apparatus is to be preferred. This apparatus should always be kept in the surgery of the practitioner and be sterilized before use each day. The patient must not be allowed this method for home use, because of the possibility of introducing secondary infection.

For the purpose of injecting the urethra, a small all-glass syringe with a blunt point should be prescribed, and the physician should give instructions as to its use. The patient is allowed to treat himself at home by this method, injecting one of the organic silver salts which will later be described.

By the use of irrigating solutions we can only hope to destroy and wash away the organisms on the surface, together with the pus and mucus, thereby rendering the mucous membrane an unsuitable medium for the growth of bacteria. At the same time they promote drainage, and when used in suitable strengths create certain tissue responses. They are best prescribed in weak solution, and no good purpose can be served by prescribing them in strong solution, for the reason that they promote too much tissue response and thereby damage the tissues, sometimes beyond repair. The same can be said with reference to solutions for injecting the urethra by means of the small syringe.

Many antiseptics have been prescribed for the treatment of gonorrhœa, most of them proving their worth, but it is generally considered that potassium permanganate, used in a strength of 1 in 8,000 for irrigating purposes, is the most suitable. For injection of the anterior urethra, one of the organic silver salts is best prescribed, preferably protargol 0.25 per cent to 0.5 per cent and for the posterior urethra, argyrol 5 per cent.

In treating the urethra particular care must be observed in the prevention of trauma, which is the most common cause of complications. For the technique of irrigation and injection the reader is referred to the recognized textbooks.

The routine treatment of acute gonorrhœa of the anterior urethra consists in daily irrigation with potassium permanganate solution (1 in 8,000) and injection of protargol solution (0.25 per cent) two or three times a day as well. The solution must not be allowed to enter the bladder in the early stages. When the disease runs a normal course, this method of treatment is continued until the symptoms and signs disappear, with the exception that in the decline the number of injections is decreased. At every visit a macroscopic examination of the urine is made, for by this means one is able to follow the course of the disease, and also frequent smears from the discharge should be examined, the number of pus cells, epithelial cells, and the presence or absence of gonococci being noted. When many epithelial cells are noted in the smear, it means that the treatment is too severe.

It is bad practice to insert a sound, bougie, medicated or otherwise, into the urethra, in acute cases, or even to pass a soft catheter, except in acute retention of urine as a last resource. The treatment of acute gonorrhœa by means of medical diathermy, although never very popular, has fallen into disuse.

No mention has been made so far of abortive treatment, for the reason that, although it is obvious that the earlier the infection receives treatment, the shorter the duration of the disease, this result is obtained by the ordinary methods of treatment above described just as quickly and very often more effectively than by the more enthusiastic methods advocated.

When strong solutions are used in an attempt to abort gonorrhœa, the tissues are devitalized, and irreparable damage is done in the shape of infiltrations of the urethra.

Certain acute complications sometimes arise during the course of acute gonorrhœa, such as paraphimosis (which is treated by immediate reduction), intense swelling of the *glans penis*, abscess of Tyson's glands, and periurethral abscess, the latter conditions being treated by bathing with hot water or hot fomentations. Early incision of Tyson's abscess is recommended, otherwise it might rupture into the urethra and cause urinary fistula, but in periurethral abscess, incision is not resorted to until the abscess points on the skin surface. In hyperacute conditions it is advisable not to begin treatment for a few days.

One must always be on the lookout for the onset of posterior urethritis, which may happen at any time after the first few days. It is usually ushered in by the lessening or disappearance of the discharge, more or less urgent frequency of micturition, with varying degrees of pain at the end of the act, and perhaps the expression

of a few drops of blood. Frequently there are no symptoms other than that the urine becomes turbid; this explains the reason why it is so necessary to examine the urine before treatment. When the posterior urethra first becomes involved it is necessary to suspend all forms of local treatment, to advise rest and prescribe morphine, 0.015 gramme (one-quarter of a grain) suppository or oral treatment combined with hot sitz-baths until the acute symptoms disappear and the act of micturition becomes normal again. Then urethro-vesical lavage may be commenced, using potassium permanganate solution (1 in 8,000) or injecting 5 per cent argyrol solution into the posterior urethra by means of a small syringe. These manipulations must be carried out with the utmost care, and unless the practitioner is sure of his technique and is confident that he is not going to produce trauma, they should not be attempted, otherwise severe and long-lasting complications may arise. When the posterior urethra becomes infected, the prostate and vesiculae seminales frequently become involved, either mildly or sometimes severely. Acute inflammation of these organs is treated on the same lines as acute posterior urethritis. When abscess formation takes place, combined with retention of urine, immediate prostatotomy should be performed. Examination *per rectum* should never be performed whilst the disease is in its acute stage except for the purpose of detecting an abscess. When the acute and subacute stages have subsided, the disease becomes localized in certain areas, such as the Littre glands of the anterior urethra or perhaps the prostate gland or seminal vesicles. It then becomes necessary to eradicate the infection by means of dilating the urethra with curved metal sounds and topical treatment by means of the urethroscope, and also by massage of the prostate and seminal vesicles.

One is unable to lay down any set time for the cure of acute gonorrhœa, because it depends entirely upon the many considerations which have been described in this article.

NORMAL M. GIBSON, M.B. (Sydney).

Reviews

STARLING'S PRINCIPLES OF HUMAN PHYSIOLOGY.—Edited by C. L. Evans, D.Sc., F.R.C.P., F.R.S. Sixth Edition. London: J. and A. Churchill, 1933. Pp. xiii plus 1122, with 562 illustrations, 10 in colour. Price, 24s.

Starling's Physiology is probably read by more medical students than any other book on the same subject. To assimilate its contents from cover to cover—no mean task, as there are now over eleven hundred well-filled pages—is to ensure an easy passage through practically any examination on physiology.

This is the second edition since Professor Starling's death, the last edition appearing in 1930. Even in this short time, the work that has been done on the subject has necessitated very considerable changes and some of the chapters have been entirely re-written. A feature of this edition is the inclusion of a few select references; as the editor points out, these do not claim to be comprehensive, because there are 4,000 papers on physiological subjects published each year.

A special word of praise is due to the publishers for keeping down the price of this book to twenty-four shillings. It is very difficult to see how they have achieved this, as the book itself bears no signs of the exercise of the strict economy that must have been necessary.

It is not necessary for us to add any words of recommendation; it is sufficient to draw attention to the fact that a new edition of the best book in the world on physiology has been published.

SYNOPSIS OF SURGERY.—By E. W. Hey Groves. Tenth Edition. Bristol: John Wright and Sons, Ltd. Pp. viii plus 693, with 163 illustrations. Price, 17s. 6d.

For the past twenty-five years this book has had an established reputation amongst candidates preparing for examinations, and it may be safely predicted that the tenth edition will be as popular as its predecessors. The author has the gift of being able to compress the maximum amount of material into the smallest possible space consistent with completeness and assimilability, and his wide experience as an examiner has enabled him to give the student just what he requires.

In this edition the text has been brought up to date and, in parts, entirely re-written. Sections have been added dealing with the position of radium in the treatment of malignant disease, the surgery of the sympathetic system, and the Winnett-Orr treatment of bone sepsis. The temptation to include controversial matter has been resisted and conciseness has been achieved without making the text unreadable. To those who are able to profit from the use of a synopsis, this book can be recommended.

J. C. D.

INTERNAL DERANGEMENTS OF THE KNEE-JOINT.—By A. G. Timbrell Fisher. Second Edition, Revised. London: H. K. Lewis and Co., Ltd. Pp. xiv plus 205, with 120 illustrations. Price, 15s.

It is a matter of common experience to find a surgeon faced with obscure symptoms suggesting an internal derangement of the knee-joint, and torn between the possibilities of unnecessarily removing a healthy cartilage or dismissing a genuine disability with an injunction to 'paint it with iodine'. The subject has often been neglected in the past, and it is scarcely to be wondered at that some patients have sought relief from the quack and charlatan in the belief that the remedy lies in the application of some form of manipulative magic. As is pointed out in a preface by Sir Arthur Keith, the only form of curative magic is that founded on a thorough and accurate knowledge of structure, function and disease, and Mr. Timbrell Fisher has done a service in putting a complex and difficult subject on a scientific basis.

The second edition has been revised and partly re-written, with the inclusion of some original new matter. The book is attractively presented and the reproduction of the illustrations is excellent. It may be recommended to the general surgeon not only as a work of reference, but as an interesting book which can be profitably read in odd moments.

J. C. D.

DISEASES OF THE SPINAL CORD.—By Williams B. Cadwalader, M.D. London: Baillière, Tindall and Cox, 1933. Pp. xviii plus 204, with 72 figures in the text. Price, 29s.

Diseases of the Spinal Cord is an addition of considerable value to neurologic literature. In its range, it is comprehensive and thorough, and describes the various diseases that affect the spinal cord in all their aspects. The arrangement of the subject-matter and the grouping of the diseases show clearly an appreciation of the needs of the student and it is likely to stimulate a logical growth of ideas and an independent mode of thinking. A study of the essentials is a prerequisite to the knowledge of pathological processes and in no other branch of medicine is this principle more applicable than in the study of nervous disorders. The author has shown admirable judgment by discussing the anatomy and physiological functions of the spinal cord before proceeding to the nervous lesions. The neuron theory, the basis of all reasoning in neurology, the effects of degeneration, the reflexes and the reflex actions are all described from the view-point of physiologists. Syphilis of the spinal cord has been exhaustively dealt with. The treatment of nervous diseases is still in its infancy and therefore much light could be thrown on this part

of the problem. The author however does not claim too much for any one of the particular lines of treatment usually adopted.

The get-up is excellent. There are quite a large number of original photographs, and drawings of considerable value and artistic merit. The book will be very useful to neurologists and those interested in allied problems.

R. N. C.

PRACTICAL HAEMATOLOGICAL DIAGNOSIS.—By O. H. Perry Pepper, M.D., and David L. Farley, M.D. London and Philadelphia: W. B. Saunders Company, Ltd., 1933. Pp. 562. Illustrated. Price, 30s.

On picking up this book the reviewer received two mental impressions: one was that there was scarcely room in his library for another book of this kind, and the other that with so limited a scope the book must contain a great deal of padding. These first impressions were both wrong. The book is confined entirely to haematological investigations. Under each heading there is usually more than one method given, but there is no enumeration of all the possible, and impossible, methods just to fill up space; the methods are well selected, obviously by writers of practical experience.

Let us take as an example the chapter on the blood platelets; this covers 16 pages. The origin and development of the platelets has been discussed in a general chapter earlier in the book. Their physical properties, physiology and the mode of their destruction are detailed. There is a paragraph on the normal variations of this element of the blood; on this matter there are considerable differences of opinion and the conclusions of more than one observer have had to be given. Three different methods of counting platelets are given in detail. Then the variations from the normal, their significance and the artificially induced and diseased conditions, under which increases and decreases are found, are discussed. There is a section on the methods of increasing the count in the thrombocytopenic state; and finally a page is devoted to the differential platelet count.

The book is divided into three parts: the first is on the component parts of the blood, the methods of studying them and the significance of variations from normal; the second gives blood pictures in diseases of the haematopoietic system; and the third deals with the haematology of diseases that are not primarily diseases of the blood or blood-forming organs.

The book is well annotated, and there are a few very useful illustrations. It is a book that we can recommend to the haematologist.

L. E. N.

THE DIFFERENTIAL DIAGNOSIS OF ENDOCRINE DISORDERS.—By Allan Winter Rowe. London: Baillière, Tindall and Cox, 1933. Pp. x plus 220. Price, 23s.

THE science of endocrinology is of comparatively recent origin and is still in the melting pot. The ideas regarding the physiology and pathology of the various endocrine glands and their functions have not yet taken definite shape and every physician and specialist will admit the difficulty that so commonly arises in diagnosing and grouping the different endocrinopathies. Though voluminous literature has gathered on the subject, these are more of a theoretical than a practical nature, and consequently are not directly useful to the practitioner. Dr. Rowe has presented, in a systematic and concise way, the data collected during 20 years of intensive research in the course of which more than 5,000 individuals have been studied by a large group of clinicians and laboratory experts. The labour and energy involved in the execution is indeed enormous and Dr. Rowe is to be congratulated on this work.

The book is divided into three main sections: Section I deals with miscellaneous matters and clinical considerations including various methods of physical examination and history taking. Section II deals with

SEPT., 1933]

all the chemical and biochemical changes encountered in endocrine disorders and contains a full description of individual methods to be adopted. This will be especially useful to all laboratory workers who would like to pursue the subject. In the assessment of the value of the various laboratory tests, the author has shown a keen sense of discrimination and breadth of view and has not allowed himself to be carried away to a diagnosis on the basis of one test alone. Section III deals with special examinations including clinical, laboratory and roentgenological procedures. The bibliography is well chosen and the book will strongly appeal to those practitioners who are interested in endocrine disorders.

R. N. C.

PSYCHOLOGY OF SEX.—By H. Ellis. London: William Heinemann (Medical Books), Ltd., 1933. Pp. xii plus 322. Price, 12s. 6d.

A CERTAIN amount of knowledge on sex psychology is now a necessity for the general practitioner, but it has been difficult to know where this knowledge may be acquired, because most of the smaller books that have appeared on this abstruse subject have been written by persons obviously not competent to carry out the task they have undertaken, and the larger books cover such a wide field that a busy practitioner or student becomes bewildered with the lengthy theoretical arguments, these books contain, and has not time to sort out, what is for him, the grain from the chaff. The result is that in all probability, after reading one of these advanced treatises, he will have a confused idea that all his patients are victims of repressions, many apparently quite harmless, and that if by suggestion he can turn these repressions into obsessions all will be well.

The *Psychology of Sex* is the type of book for which the practitioner and student have long been waiting, for within its three hundred and thirteen pages Havelock Ellis has condensed the essentials of his own much larger works as well as drawing on the continental writers on sex psychology, and he has produced a well-balanced presentation of the subject, which does not overemphasize the importance of a knowledge of sex in general medicine and which will give the student and the general practitioner all the information they are likely to need in the ordinary course of their work, but the possibility of more detailed knowledge being occasionally needed is catered for by the addition of a few references at the end of each chapter.

Prophecy is an unsafe practice in which to indulge as a general rule, but the reviewer feels he is on safe ground in stating that this book will be the textbook on this subject for English-speaking students and practitioners for many years to come.

P. A. M.

COLDS AND HAY FEVER. (MINOR MONOGRAPH SERIES).—By Frank Coke, F.R.C.S. London: Baillière, Tindall and Cox, 1933. Pp. x plus 148. Price, 5s.

THE common cold is one of the heritages of civilization. It is also a perpetual thorn in the side of the general practitioner, for most of the patients—or at any rate their mothers or aunts—have 'cures' which, if no better than those he himself can suggest, are seldom any more ineffectual. However, the physician is still expected to make suggestions for the prevention and cure of this most tiresome complaint, and he will find quite a number of useful hints provided in this book.

Hay fever is looked upon as rather a joke by everybody but the people who suffer from it; to these it may amount to a tragedy. It is funny to recount the story of the Harrow boy who sneezed sixty-seven times in succession, but when you have sneezed a thousand times in twenty-four hours you often feel more like making a violent departure from an unsympathetic world than joining the deriding laughs of your friends or listening

to the facetiae of your attending physician. In this matter also Dr. Coke has some useful suggestions and it is obvious that he at least does not underrate the importance of this condition when he suggests a course of treatment, which is to be carried out over a number of years before complete success can be expected. We notice that the author adopts the popular misspelling, 'wheal' for weal. It is a curious fact that h's always seem to give trouble—at the beginning of a word if you are hypo- and in the middle if you are hyper-educated.

A STUDENTS' MANUAL OF BIRTH CONTROL.—By L. C. Butler, M.R.C.S., L.R.C.P., D.P.H. Published by Noel Douglas. London. Pp. 39. Price, 1s. 6d.

THE fountain of books on birth control seems inexhaustible, and we must assume that the demand is the same. This particular book has points for recommendation. It is short, the author sticks to the point, and she is apparently orthodox. She is not dogmatic nor on the other hand too vague. Various birth-control methods are given in concise detail together with their advantages and disadvantages. The author might be accused of laying too much emphasis on the commercial aspects of birth control, as she gives the names and addresses of the manufacturers of appliances, etc., throughout the text, but we do not take this view and we consider that this particular practice adds to the usefulness of the book.

STREPTOCOCCI IN RELATION TO MAN IN HEALTH AND DISEASE.—By Anna W. Williams, M.D. London: Baillière, Tindall and Cox. Pp. xii plus 260. Plates 8. Price, 29s.

THERE are perhaps no other groups of bacteria that can claim such a volume of literature and such intensive study during recent years as those included under the genus streptococcus. This monograph contains a full and up-to-date account of the part played by streptococci in health and disease. The methods of isolation and studying the streptococci are fully dealt with. The work is of particular value because the author has devoted special attention to the subject for several years. A useful bibliography of the literature is appended.

There are unfortunately several mistakes in the text both in the style and in spelling and we cannot help feeling that the work would have been much improved if more attention had been paid to literary style. We hope that a very thorough revision will be made of this excellent book before the next edition. We can strongly commend this book to those interested in the very important genus of bacteria—the streptococcus.

OTHER BOOKS RECEIVED.

1. *Woman's Periodicity.* By Mary Chadwick, S. R. N. London: Noel Douglas. Price, 6s.
2. *The Technique of Contraception—An Outline.* By E. M. Matsner, M.D. Published for the American Birth Control League, Inc., New York, by the Williams and Wilkins Company. Baltimore. 1933. Price, Re. 1.
3. *Qualitative Analysis.* By N. M. Shah. Published by The Students' Own Book Depot, Dharwar. Second Edition. Price, Annas 12.

Annual Reports

ABSTRACT OF THE ANNUAL REPORT OF THE DEPARTMENT OF PUBLIC HEALTH, YEAR ENDED 30TH JUNE, 1932. UNION OF SOUTH AFRICA

Malaria in Natal.—The malaria epidemic which occurred during the autumn was the worst yet experienced in Natal.

But disastrous as this epidemic has in many respects proved, there has yet emerged the fact that human communities are by no means helpless even in the most adverse climatic circumstances. Propaganda is gradually bearing fruit and communities that conscientiously carried out the simple precautions have escaped with little or no infection, while their neighbours suffered grievously.

The little Indian village of Umzinto escaped malaria, though surrounded on all sides by infection, and constantly traversed by vehicles bringing natives from badly infected areas to local doctors for treatment. The community is supervised by a voluntary Indian Committee employing an Indian trained in anti-larval work. A sluggish river passes through the village and numerous seepages everywhere provide ideal breeding-places. But every possible *costalis* breeding-place was visited once weekly by the trained Indian, who dealt successfully with all of them, as proved by results.

This instance is quoted as strikingly illustrating Professor Swellengrebel's reiterated assertion of the localization of the malaria vectors and the comparative simplicity of control. In essence, this amounts in Natal to making certain that every *costalis* breeding-place is found and dealt with once weekly.

In striking contrast with Umzinto were the conditions obtaining in the towns of Stanger, Verulam and Umkomaas, where the incidence of malaria was the worst of any in Natal towns. Systematic search for and treatment of breeding-places was not made. None of them employed a qualified inspector and the first two towns mentioned did not even avail themselves of the opportunity of sending an official down to the Government classes in Durban for training in anti-larval methods.

As examples of other communities that were kept virtually free of malaria as the result of well-supervised anti-larval methods may be mentioned the Umlhlanga Rocks Health Board and the Greenwood Park Health Board. Both of these had reason to be very well satisfied with the results of their efforts.

The sugar industry as a whole suffered less from malaria this year than in previous years. This again can be attributed very directly to improved anti-larval methods.

It cannot be too often reiterated that malaria is a local disease requiring to be combated by local measures which can usually only be effectively enforced by a properly constituted local authority thoroughly alive to the menace.

Transvaal.—In no part of the Transvaal did the incidence of malaria reach epidemic proportions.

The value of the drug plasmochin in rendering human carriers of malaria non-effective to mosquitoes is being investigated. The work carried out this season has demonstrated satisfactorily that the infective forms of the malaria parasite in man are destroyed by the drug when exhibited in suitable dosage. But the experiments have not influenced the infectivity rate of the mosquitoes in the area. This failure appears to be due to a very rapid turn-over of the mosquito population in native huts.

REPORT OF THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE FOR THE YEAR ENDED 31ST JULY 1932

This report is a record of continued expansion ever embracing a wider field of activities. Teaching has always been the chief function of the London School, and now even more time has had to be devoted to this side of the work on account of having three qualifying courses instead of two for the D.T.M. & H. The world-wide influence of this school is indicated in the tables on page nine showing that fourteen countries sent students during the year and over twenty-one countries

received these same students after their training; one came from Iceland and apparently returned there!

In the report of the division of clinical tropical medicine we note that '..... many natives suffering from different tropical diseases.....' The italics are our own, for it is a surprising thing to find a man of the long experience of tropical medicine enjoyed by the director of this division using a term of this kind. Surely in a report written in London the word native should be taken to apply to cockneys and we do not suppose this class were sufferers from the long list of tropical diseases cited as being available for demonstration during the year.

In spite of the many calls on the staff for teaching a great deal of research has been carried on, but in certain of the divisions notably those of bacteriology and immunology, biochemistry and chemistry, and epidemiology and vital statistics much of the work has no direct bearing on tropical problems. This of course does not detract from its value but is an indication that the London School is daily becoming a more important centre to the whole empire for the study of problems in medicine and hygiene.

As usual the division of medical zoology in all its departments, namely protozoology, helminthology, and entomology, presents a record of active research for the year.

The close connection the school has always had with India is still further strengthened by the appointment of Colonel S. P. James, I.M.S. (Retd.), as lecturer in the epidemiology of malaria, and the school is fortunate in having Sir Rickard Christophers, I.M.S. (Retd.), working in co-operation with the staff. Incidentally, Sir Rickard was not Director of the Malaria Survey of India, but of the Central Research Institute at Kasauli.

REPORT OF THE HEALTH ORGANIZATION FOR THE PERIOD JANUARY 1931 TO SEPTEMBER 1932. LEAGUE OF NATIONS, GENEVA. OFFICIAL NO. A. 28. III

Malaria Commission

EARLY in 1931, the Malaria Commission had to deplore the death of its Chairman Professor V. Ascoli, and Dr. Lutrario, who had been Chairman until 1930, was asked to take his place. Professor G. Bastianelli, Director of the Advanced School of Malariology, Rome, and a member of the Health Committee, was elected a member of the Commission in June 1931.

The Commission has continued its study on the efficacy of anti-malaria medicaments which might be prescribed instead of quinine, the present price of which constitutes a serious obstacle to the treatment and prevention of malaria. Of these medicaments, the Commission recommended the secondary alkaloids, mixtures of alkaloids and the total alkaloids of cinchona. After a consultation of experts held in London on 16th January, 1931, the Commission met at Geneva on 5th and 6th May to consider the standardization of the total alkaloids and mixtures of alkaloids. It proposed that the name 'Quinetum' should be reserved for a preparation consisting of quinine, cinchonidine and cinchonine in equal parts, that being approximately the normal proportion of these alkaloids in *Cinchona succirubra*, and the name 'Totaquina' for a new standard preparation containing the total alkaloids of cinchona. This preparation should contain at least 70 per cent of crystalline alkaloids, of which not less than 15 per cent must be quinine. Amorphous alkaloids should not, however, exceed 20 per cent, mineral matter 5 per cent and water 5 per cent. This new formula was communicated to the Commissions of the National Pharmacopœia in the different countries.

In September 1930, the Malaria Commission reached the conclusion that a conference of representatives of the governments of malarial countries should be contemplated with a view to determining those countries' real requirements in quinine and discussing

measures likely to reduce the price of the medicament so as to make it available for all malarial countries. The Secretariat was accordingly requested to collect from malarial countries documentation relating to the total number of malaria cases, the number treated, and the amount of quinine and secondary alkaloids of cinchona imported and distributed annually during the last ten years. This enquiry began in January 1931 and, up to the present, no less than ninety-six countries have forwarded their replies.

The international courses in malariology instituted in 1926 under the auspices of the Health Organization were held in 1931 in Paris, Rome and Hamburg, and the Health Organization offered nineteen scholarships to medical men from twelve different countries. In 1932, these courses were held in Paris and Rome, and twelve scholarships were awarded to medical men in twelve countries. Both in 1931 and in 1932, the field work which followed the theoretical instruction was carried out in Spain, Italy and Yugoslavia.

At the request of the Siamese Government, Dr. L. Anigstein, a member of the Malaria Commission, conducted an enquiry from 15th January to 27th April, 1931, into malaria and anophelines in Siam. His report was published in No. 2 of the *Quarterly Bulletin*.

On returning from his tour in China, of which a summary is given below, Professor M. Ciuca, Secretary of the Malaria Commission, visited in turn Indo-China, Malaya, the Dutch East Indies and Ceylon for the purpose of studying the anti-malaria organization, training of staff, epidemiological conditions and quinine requirements in those countries. His mission was greatly facilitated by the kind assistance he received from those responsible for the health services and anti-malaria organizations in those countries.

In Indo-China, which he visited at the invitation of the Governor-General, an inspection of the Pasteur Institutes at Saigon and Hanoi, with which the Anti-Malaria Service is connected, enabled him to secure information as to the general plan of campaign, the methods adopted and the work done by the entomological and epidemiological branches of the Anti-Malaria Service. Under the guidance of Dr. H. Morin, Director of the Anti-Malaria Service, he visited the red earth region of Cochin-China—which, in spite of its extreme fertility, has earned the name of 'the accursed lands', owing to its devastating epidemics of malaria—the cinchona plantations of the Pasteur Institute and the malarial zone of the Tonkin mountains.

In Indo-China, the *A. maculatus*, *A. minimus* and *A. aconitus* must be considered as carriers. The campaign conducted by the Anti-Malaria Service has achieved rapid success through the combined action of quininization, both preventive and therapeutic, and measures directed against the carrying species of anopheles—e.g., subsoil and open drainage, the abolition of water collections, oiling. Thanks to the results already obtained, the area in which the anti-malaria campaign is being pursued is continually increasing; the local authorities show a new spirit and spontaneously request the Anti-Malaria Service to undertake sanitation work of which they will bear the cost.

At the Hanoi Medical School, Dr. Ciuca was invited to open the first course in malariology organized by the Anti-Malaria Service. The work of the League of Nations Malaria Commission and the principles of the anti-malaria campaign with reference to local conditions formed the subject of this first lesson. It is intended to extend this course next year, so that other malarial countries in the Far East may profit by it.

Subsequently, Dr. Ciuca visited Singapore, Penang and the Malay States. His work was greatly facilitated through the good offices of the Director of Health and Medical Services in Malaya, Dr. C. J. Wilson. The *A. maculatus* is chiefly found in the hill district, whereas in the collections of brackish water in the coast zone the *A. ludlowi* may be a dangerous carrier. In Malaya, the campaign against malaria is directed against the carrying species in its larval stage. A protective zone

is established around groups of dwelling-places, after the breeding-places of the larvæ have been eliminated through drainage of the soil, either permanent or temporary in character, according to local conditions. At Kuala Lumpur, Dr. Ciuca was able to collect information concerning an attempt at mass prophylaxis by means of plasmoquine carried out on 300 coolies of a rubber plantation by Dr. A. N. Kingsbury, Director of the Institute for Medical Research.

In Java, under the guidance of Dr. Soesilo, Head of the Anti-Malaria Service, Dr. Ciuca studied the central anti-malaria organization, the training of staff, the methods of the anti-larvæ campaign, the cinchona plantations and the quinine factories. The *A. ludlowi*, the breeding-places of which extend all along the coast, is here the chief carrier; in the mountain region the *A. maculatus* and *A. aconitus* are found and transmit malaria up to an altitude of 1,200 metres. Near Batavia, Dr. Ciuca was able to examine the sanitation work undertaken under the direction of Professor Walch according to an original biological method in the enormous fishponds at Passerocean. The principle adopted is the destruction, through partial and periodic drainage of these ponds, of the floating weeds which constitute the breeding-places of the *A. ludlowi*. The results of this work are seen in a heavy decrease in malaria, the spleen rate in the neighbouring villages having fallen from 68 to 7, 5, 2 and even 0.

In Ceylon, under the guidance of Mr. Carter, entomologist, Dr. Ciuca studied the central and local organizations of the anti-malaria campaign. The setting up of an entomological service in 1921, under Mr. Carter's direction, made it possible to prepare a malaria chart of the island where infection is due to the presence of *A. culicifacies* and *A. listoni*.

Opium Commission

The 1925 International Opium Convention laid upon the Health Organization a twofold duty:

(1) To exempt from the measures of international control set up by the Convention preparations which, while coming within its scope owing to their composition, are not liable to give rise to the drug habit (Article 8), and

(2) To bring within its scope narcotic drugs to which it does not yet apply but which present the same dangers as those drugs which it has placed under control (Article 10).

With regard to the first of these tasks, the Health Committee concluded its examination of the lists of preparations which the Governments of the Argentine, Austria, the United Kingdom, Bulgaria, Estonia, France, Germany, Hungary, India, the Irish Free State, Latvia, Poland, Roumania, Siam, the Union of South Africa, the Sudan, Sweden and Switzerland had proposed to exempt from the provisions of the Convention, and a recapitulatory list of all the preparations thus exempted was published (document C.114.M.54.1932. III).

The Health Committee also continued the work involved by Article 10 of the Convention, and brought within the scope of the latter:

(1) A new narcotic drug: acedicone (acetylodemetlylodihydrothebaine) together with its salts, and the preparations containing it;

(2) All those substances enumerated in Article 1, paragraph 2, group I, of the Convention for Limiting the Manufacture of Narcotic Drugs which were not yet covered by the 1925 International Opium Convention.

Continuing its work on the standardization of the methods of ascertaining morphine content in the various opiums, which was referred to the Health Committee in 1931, the Commission of expert pharmacologists, under the chairmanship of Professor L. van Itallie, of Leyden, held its second session at the Hague, 11th to 14th July, 1932.

Before proceeding to the codification of a standard method, the experts thought it necessary to carry out

researches regarding a new method worked out by Professor Eder, of Zurich, and also the method based on the British Pharmacopœia, recommended by Professor van Itallie.

The Commission also drew up a scheme for the investigation of the standardization of methods of ascertaining the cocaine content of coca leaves. This scheme will be submitted to the Health Committee at its next session.

The Commission hopes to conclude its work in the spring of 1933.

At the request of the Advisory Committee on Traffic in Opium, the Health Committee undertook to study modern methods for the treatment of drug addicts in the various countries. An interim report was prepared by Dr. P. Wolff, of Berlin.

The Permanent Central Opium Board asked for the Health Committee's opinion on a new method of estimating the consumption of narcotic drugs. The study of this method, by which the total consumption of opiates is expressed in the number of average doses per head of the population, instead of in milligrammes of raw opium, was referred to a group of experts whose work is still proceeding.

Commission on the Fumigation of Ships

Influenced no doubt by the increasing importance of the fumigation of ships from the international point of view, owing to the provisions of the International Sanitary Convention of 1926 coming gradually into force, the Health Committee, in consultation with the Permanent Committee of the Office International d'Hygiène Publique, set up in the spring of 1928 a Commission on the Fumigation of Ships.

The first meeting of the Commission took place in Paris on 14th May, 1928, under the chairmanship of Surgeon-General H. S. Cumming. It drew up a programme of work and accepted with gratitude its Chairman's offer to organize experiments with regard to the fumigation of vessels by means of hydrogen cyanide in order to determine more exactly the value of this process, particularly in respect of:

(a) Its efficiency to destroy rats with the cargo *in situ*;

(b) The effect of the gas on different cargoes;

(c) The question of pocketing; and

(d) The influence of temperature, humidity and like matters.

At a plenary meeting of the Commission in May 1929, the chairman presented an interim report which summarized the replies he had received in response to his request for information on the methods of fumigation in force and the results achieved in the principal ports of the world, and suggested a programme of experimental work, which was approved.

In September 1931 a committee of experts composed of Dr. H. F. de Bruyne, Chief of the Disinfection Service, Rotterdam; Dr. W. Dreyer, Port Health Officer, Bremen; Dr. T. W. Monier-Williams, of the Ministry of Health, London; Dr. P. G. Stock, of the Ministry of Health, London; Dr. Ch. Vigne, Chief of the Port Sanitary Service, Havre; Dr. A. Vila-Rodriguez, of the Port Health Station, Cadiz; Dr. C. L. Williams, of the Quarantine Station, Staten Island, New York, investigated the work carried out in the United States on behalf of the Commission. The experts visited New York, Washington and Baltimore, where the Federal authorities had arranged for their benefit a number of demonstrations on the fumigation of ships by the various methods employed in the United States.

They were particularly interested in visiting the quarantine stations, warehouses and shipbuilding yards, and had an opportunity of discussing with the officials of those establishments the various aspects of fumigation: efficiency and dangers of the various methods, disadvantages of certain fumigants for the cargo, rat-proofing, the preparation of ships for fumigation, methods of ventilation, etc.

At the conclusion of their visit, the committee of experts drew up a report reviewing the practical investigations carried out by the United States Public Health Service, and indicating how far the results obtained provided answers to the questions set out in the programme drawn up by the Commission on the Fumigation of Ships.

This report was discussed in detail at a plenary meeting of the Commission in April 1932, and the reader will find the Commission's conclusions in No. 2 of the *Quarterly Bulletin*.

Leprosy Commission

A Conference on Leprosy, organized by the Leprosy Commission of the League of Nations, was held at Bangkok in December 1930 during the Eighth Congress of the Far Eastern Association of Tropical Medicine. Its report was published in document C.H. 970.

The members of the Commission were also invited to attend the Conference on Leprosy of the Leonard Wood Memorial for the Eradication of Leprosy held at Manila in January 1931. The report of this Conference was published in English in the *Philippine Journal of Science*, Volume 44, No. 4, April 1931, and in French in the *Revue d'Hygiène*, Volume XLIV, No. 6, 1932. While the report drawn up by the Leprosy Commission at Bangkok lays down the general principles of prophylaxis, the report of the Manila Conference contains technical conclusions and information. Both state that greater uniformity should be introduced into the study of leprosy. The standardization of treatment presents very great difficulties. The first step in this direction would be to introduce systematic comparisons, such as are already made by several institutions dealing with leprosy. A beginning might be made by:

(1) Comparing two equivalent groups of subjects placed in the same circumstances, one only of which would receive treatment by chaulmoogra;

(2) Making a further experiment of the same kind to determine the value of intradermal injections;

(3) Analysing observations on a sufficiently large number of patients who have undergone continuous treatment, grouped according to the form of the disease, its gravity, etc., with a view to obtaining information as to the conditions of and reasons for the success or failure of the treatment;

(4) Formulating those methods for the preparation of oils and esters which are recognized to be most satisfactory.

In April 1931, the Brazilian Government made an offer to the Council of the League to establish an international centre for research on leprosy under the auspices of the League at Rio de Janeiro. This centre was to be legally separate from the League and entirely autonomous, the Brazilian Government undertaking to bear the whole cost of maintaining and working the centre. The League accepted this offer, and the centre, with a representative of the League of Nations, a representative of the Argentine Republic and a representative of Colombia will sit on its governing body.

ABSTRACTED FROM THE ANNUAL REPORT OF KASHMIR MEDICAL MISSION OF THE CHURCH MISSIONARY SOCIETY FOR THE YEAR 1932

THIS report gives a record of strenuous work for the year 1932. This hospital is of special value because it brings the people of Kashmir into touch with skilled medical and surgical assistance. The following figures indicate the amount of work done by this hospital during the year:

There were 20,771 new out-patients, with a total attendance of 50,453, and the in-patients numbered 2,199. In addition to the work at headquarters certain members of the staff go on tour from time to time and in this way treat many persons who are not or cannot be attended to in government dispensaries. Subscriptions to this deserving charity may be sent to Dr. E. F. Neve, Mission Hospital, Srinagar, Kashmir.

ABSTRACTED FROM THE BRITISH GUIANA
MEDICAL ANNUAL FOR 1932. TWENTY-FIFTH
YEAR OF ISSUE

The major portion of the book is devoted to clinical and pathological records of cases of special interest occurring in the various hospitals in the colony. All of these papers might be read with advantage by tropical practitioners anywhere in the world as they are essentially practical in character.

The latter portion of the annual gives a full record of the British Medical Association meetings in British Guiana which is followed by a number of abstracts of papers read at some of these meetings.

The small book is of handy size and it is bound in stiff card-board which makes it easy to hold and therefore all the more pleasant to read, and it is also printed on remarkably good paper for a publication of its nature.

ABSTRACTED FROM THE ANNUAL REPORT OF
THE KING EDWARD VII SANATORIUM,
BHOWALI, UNITED PROVINCES, FOR THE
YEAR 1932

This sanatorium which was established in 1912 by the people of the United Provinces of Agra and Oudh for the treatment of early cases of pulmonary and laryngeal tuberculosis, continues to do valuable work as is indicated by the annual report for 1932 which we have just received.

On account of its altitude and the intense cold in winter the sanatorium is only open from March to December each year, but even so, with accommodation for 'nearly 110' patients, the returns show that 180 cases were dealt with in 1932. This is not a free institution except for a very few patients but the scale of fees payable is small. At the end of the report the rules, scale of fees, how to obtain admission, etc., are given in full.

'NURSING EDUCATION AND SCHOOLS OF
NURSING' (METHODS AND PROBLEMS OF
MEDICAL EDUCATION) 21ST SERIES. PP. 226.
ILLUSTRATED. PUBLISHED BY THE ROCKE-
FELLER FOUNDATION. 1932

This is an arrestingly interesting account of nursing education in various countries, including America, Canada, China, Denmark, England, Finland, France, Hungary and Siam. It gives a wealth of detail of the actual methods of training nurses, and of post-graduate study, in which America and Canada are particularly progressive, of the problems and difficulties which arise owing to the combination of a great amount of theoretical study with the actual nursing of the hospital wards, of financial difficulties which arise and the means available to meet them.

In America and Canada great stress is laid on the importance of a university training for nurses in conjunction with the general hospital training, pre-graduate or post-graduate. To quote from the opening article (Yale University School of Nursing) 'the importance of University relationship cannot be over-emphasized for it has made possible within a comparatively few years an evolution of the programme of nursing education that could be realized only through the freedom for study, experimentation and demonstration that such a relationship permits'. In the second article (Cook County School of Nursing, Chicago) 'the alert, sensitive, refined type of woman needed to serve in the various fields of nursing, in which she often carries the responsibilities of life and death, is more apt to be found at a University securing her education'.

The impression received on reading the various articles, particularly those from America and Canada, is the great consideration for the nurse or student during her training, and the absence of methods which prevail in many older hospitals where the primary object is the achievement of the daily ward work, without due consideration for the thorough training of the nurse.

In hospitals, where understaffing is so prevalent, the training or 'nursing education' of the nurse has often to be a secondary consideration. It would have been interesting if the ratio of nurses to patients, during the training of nurse-students in America and Canada had been included; the question presents itself to a practical mind as to when the actual nursing of the patients, and all that this entailed, was done. One feels quite sure that the ratio will be an adequate one, so that the progressive methods described will be possible of achievement.

The history and development of nursing education in Teacher's College, Columbia University, is of great interest as it shows the importance and extreme usefulness of special training for the senior appointments in hospitals and it must turn out women highly qualified for the important positions of administrators of training schools for nurses, teachers in schools of nursing, public health appointments, etc. The history of nursing education is fully described and is of absorbing interest.

The article regarding development of nursing and schools of nursing on page 6 (from the Vanderbilt University Nursing School) should not be missed as it acknowledges many practical problems which arise in the training of nurses, and contains clarifying paragraphs such as 'a certain proportion of nursing schools have been created because hospital authorities thought they saw in them a good economic investment' or again 'It is quite obvious that these hospital authorities have been quite unaware of the social significance and social worth of nursing to the community' and again 'the function of the nurse has changed considerably during the past twenty-five years as a direct result of the advance made in the knowledge of science as it is applied to sickness and health—each year the nurse has been called upon to assume increasingly complex and responsible technical duties. She requires therefore an increasingly richer science background and a greater understanding of medicine which the nursing curriculum does not as yet provide'. Reference is also made to one of the basic principles laid down by Florence Nightingale that it is necessary for the nurse to be a woman of refinement and culture, because the art of nursing can never be practised by the mentally dull or by untutored individuals of no social graces. Information of a very useful kind is also given regarding 'nursing and the hospital' and the necessity for the inclusion of nursing in the hospital budget and its due importance. It deplores the fact that many hospitals treat the department of nursing as a non-revenue bearing unit, instead of showing in the hospital accounts the revenue derived from the nursing service which may run into thousands of dollars.

Other interesting articles from America and Canada follow and the 'Report of a Study made by the National Organization for Public Health Nursing' in New York is especially so and suggests the linking of practice with theory in a definite way, for example:—'..... the adapting of diets ordered in certain diseases to actual conditions under which the patient lives, and the relation of the patient's occupation to his treatment'.

The importance of the out-patient departments as units of experience is clearly shown as is also the observation home-visits.

The teaching of public health nursing in Toronto shows a very sincere effort to evolve the ideal training of the nurse for this particular branch of work.

China, one gathers, is attempting to train nurses in college, with visits to the hospital wards and departments, and one reads on page 136 'that the hospital has never depended for its care of patients upon the services of the student nurses'. The description of the training might be termed revolutionary as it appears to upset the strong tradition of the training of a hospital nurse in actual practical nursing which has hitherto been considered essential.

Denmark and Finland give interesting accounts of State Preliminary Training Schools, which fill a most important place and their example might be followed

with advantage in other countries. Much of the theory of nursing is taught in these schools so that when the student nurses enter the hospitals for training their attention can be largely concentrated on the actual nursing of the patients. The schools are state subsidized and the student nurses are drafted to the various hospitals for training on completion of this preliminary course.

In England many of the great hospitals have a preliminary training school for nurses attached, which has the advantage that the student nurse is taught in actual conjunction with the hospital and works for short periods daily in the wards of the hospital to which she belongs. One felt distinct disappointment on reading the article on 'Nursing Education in England' that so little description was given of the methods in daily use in the training of the nurse in actual practical nursing. It is such a feature of the training in English hospitals and a full description would have been of great value in a book of this type.

France is making great efforts to raise the standard of nursing and the work described is very interesting and tells of the same difficulties and uphill fight to establish nursing that so many countries have experienced. It tells also of the courage which has met and overcome these difficulties.

In 1903 no uniform was worn by the nurses and the strongest resentment was expressed at any suggestion of it. The example was set by the 'Directrice' allowing, as a great privilege, the new probationers to wear the same uniform as she herself wore, with the result that shortly all the staff were asking to be allowed to wear it. There was also no night nursing at all as it was considered improper for young nurses to nurse male patients at night. A system of night nursing was started with elderly women present to act as supervisors, until prejudice was overcome. From these beginnings great developments have arisen and the account of present-day methods of training are most instructive.

The account of the Siriraj Hospital, Bangkok, puts forward its problems and schemes for the training of nurses.

It is interesting to see the importance attached to hospital house-keeping in this article. Many of the problems which arise with regard to supplies and equipment were touched on and improvements recorded in the care of the soiled linen of the hospital by the erection of an electrically-run steam laundry. The linen supply and sewing room of this hospital are under the supervision of a nurse. A very practical point mentioned was the special course of instruction given to the coolie staff in general cleaning duties by a nurse instructor.

The publication contains much information of great value and is recommended for particular study in every province in India where nursing is so much in need of reorganization and assistance. Many of its suggestions and ideas set a great example and the whole volume will be a valuable guide to hospitals wishing to provide an adequate and progressive nursing service.

ABSTRACTED FROM THE REPORT ON THE ADMINISTRATION OF THE EXCISE DEPARTMENT IN THE PRESIDENCY OF BENGAL FOR THE YEAR 1931-32

THE excise administration is perhaps the one most concerned with the control of drugs of addiction in this country. While habitual use of the narcotics, stimulants or intoxicants is a necessary corollary to civilization and more active modes of life in any country, it must be admitted that moderate use of at least some of these substances is considered necessary if not altogether beneficial. The duty of the excise department of the Government is to see that the amount used does not exceed the safety limits, and the temptation is kept as far off as possible. The problem is being vigorously attacked in all its aspects in all civilized countries, but in India where probably the addiction problem is the

oldest and most widespread, it is yet to be seriously grappled with.

Calcutta is the largest city in India and on account of its commercial importance exacts a good deal of vigilance on the part of the excise, police and customs authorities. This is one of the main headquarters of the smugglers and it is evident from the summary of the prosecutions given in the report of the administration of the excise department in the Presidency of Bengal, 1931-32, that all the alertness, skill and tact of the department is needed to control this illicit traffic. During the year under report, 9,312 persons were prosecuted for offences against excise and opium laws as compared with 8,218 during 1930-31 and 1,033 ounces of cocaine were seized. The report shows that there is a reduction in the consumption of all excisable articles (though the revenue in some cases is more) in the year 1931-32 compared with the previous year and the Commissioner rightly points out this fall is due to nothing else than the general economic depression. The policy of maximum revenue with least consumption has had the desired effect in reducing the consumption, but this cannot go beyond certain limits, and these seem to have been reached. This only points to the necessity of starting scientific investigation of the problem, from medical, sociological, and economic aspects.

Another important aspect of the administration from the medical view-point is supervision of the supplies of rectified spirit used for manufacturing tinctures and medicines. Eight bonded laboratories in Calcutta and one at Konnagar continued to manufacture tinctures and medicinal preparations during the year under report. The rules prescribing strict adherence to B. P. standards and approved recipes continued to be strictly enforced, and there was no complaint regarding the quality of the products of the bonded laboratories. The working of the bonded laboratories was on the whole satisfactory and the medicinal preparations manufactured therein continued to be freely used both in Bengal and in the other provinces, replacing to a great extent the imported drugs from abroad.

R. N. C.

ABSTRACTED FROM THE ANNUAL PUBLIC HEALTH REPORT OF THE CENTRAL PROVINCES AND BERAR FOR THE CALENDAR YEAR 1931

DURING the year under report considerable activity has been shown in infant welfare work and that this is badly needed is shown by the infant mortality rate returns which are the highest for the province since the year 1921, and which from a table given in the report are shown to be by far the highest of any of the ten provinces for which figures are given. It is true that the birth rate is also higher in the Central Provinces and Berar than anywhere else but the infant mortality rate appears to be disproportionately greater.

There appear to have been no serious epidemics during the year but the total deaths from all causes show an increase of more than 25,000 over those of 1930; all the principal headings under which deaths are recorded showed an increase with the exception of cholera, smallpox and injuries.

ABSTRACTED FROM THE ANNUAL REPORT OF THE UNION MISSION TUBERCULOSIS SANATORIUM, AROGYAVARAM, NEAR MADANAPALLE, SOUTH INDIA, 1931-32

THIS interesting report is copiously illustrated and shows the sanatorium to be situated in attractive and spacious surroundings.

There are various types of accommodation in special wards for which payment from Rs. 50 to Rs. 100 per month is charged. In the general wards the small charge of Rs. 18 a month is made for those who can afford it, but this amount may be reduced at the discretion of the medical superintendent. Indigence, however,

is not a bar to admission as anyone with a certificate from a gazetted government officer may be admitted free.

This institution appears to be deserving of public support.

ABSTRACTED FROM THE ANNUAL REPORT OF THE KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND FOR THE YEAR 1932

This report gives an account of the activities in connection with the fund. There is an annual income of over Rs. 50,000 from invested funds and less than one-third is spent on administration.

The work of the organization is mainly propaganda and education of the public and under its auspices anti-tuberculosis sub-committees have been formed in many provinces and also in Mysore. Apart from running expenses nearly all the rest of the money expended during the year was disbursed as grants-in-aid to these various local sub-committees.

This fund with its steady income and wise expenditure should in time become a valuable force in combating tuberculosis in India.

ABSTRACTED FROM THE REPORT OF THE THIRTEENTH EPIDEMIC OF PLAGUE IN THE CITY OF HYDERABAD AND ITS SUBURBS

The spread of infection in this epidemic was almost entirely by human agency, either (1) by removal of a case of plague, (2) by carrying infected clothing, (3) by entertaining relatives or friends from infected areas, (4) by visiting the sick. In all these cases infected fleas are carried in the bedding or clothing of either the sick or the healthy to the non-infected house. These infected fleas carry the disease to the rats in the new house or to the human inmates, but as a rule the fleas first infect the rats and only bite the human beings after the rats are dead. A plague-stricken rat loses its natural defence against fleas and sometimes swarms with them—enormous numbers of fleas in this way become infected and the people in the house have small chance of escaping infection. In some cases the fleas in the new house may be infected directly by the imported case of plague. It is interesting to note that when hundreds of plague cases are admitted into the isolation hospital the complete disinfection of the clothing and bedding has been sufficient to prevent a single case of infection among the hospital staff.

Direct infection by visiting the sick is likely to occur when the visit takes place at night or in dark ill-ventilated rooms. Fleas are always inactive in bright daylight.

Once the infection has been brought by human agency to a new locality, its spread from house to house in that particular area is by rats. The theory that rats move far from their burrows or migrate from fear of an epizootic is not true of the house rat in India. In and from Nurkhan Bazaar infection only spread in definite proportion to human migration. Sultanshah which is only three to four furlongs away did not show signs of infection for at least three months from the outbreak of the epidemic. The spread of infection was arrested in nine localities and though sporadic imported cases occurred in these areas later on, there was sufficient interval to establish the claim that infection had been prevented. It is interesting to note that the number of infections in new localities of the town amounted to 207: in none of these did the disease spread to a great extent. It is felt justifiable to claim that this large number of isolated infections would normally have created, first of all a very wide infection of rats, and secondly a very severe epidemic of human plague; no part of the city or Chaderghat escaped invasion by the sick and their relatives from the infected area. The area of the town of Hyderabad is 35 square miles, and including the frontier villages it

is roughly 50 square miles. The actual deaths from plague average 20 per square mile; and this includes those definitely imported from other towns. The rapid arrest of all these isolated outbreaks was possible only because a very large proportion of rats had been destroyed. Another deduction which seems justified is that all the spread was due to human agency.

X. cheopis (the dangerous flea) is the most prevalent flea in Hyderabad. The variety known as *X. astia* is found only in certain areas, and comprises 6 per cent of the fleas in Hyderabad. *Astia* is found in a far higher proportion in the Madras Presidency which consequently is usually free from plague. Hyderabad is a city, which contains an astonishing population of rats and provides all the conditions favourable for their rapid breeding. Rats breed freely in the interstices of roof tiles and the 'kutchra' walls without foundation. Most of such walls and roofs are found riddled with rat-holes. As mentioned in the last report the circumstances are so favourable for breeding of rats that it will be impossible to keep the rat population under control without persistent and continuous destruction for years to come. While this destruction is going on, it is absolutely necessary to continue the work of the City Improvement Board in providing large numbers of good type of rat-proof houses and cleaning slum areas. Rat-proof gunjes and markets are to be constructed and special attention will also be necessary for hundreds of retail grain shops.

Food is always present in unlimited supply for these pests and the public require education in this matter. In every middle- and upper-class house there are godowns for storing grain all accessible to rats. Among the poorer classes remnants of food are not thrown away. These conditions provide food for rats in unlimited supply.

ABSTRACTED FROM THE REPORT ON THE HEALTH OF THE ARMY FOR THE YEAR 1931. VOLUME LXVII. LONDON

The following abstracts have all been taken from that portion of the report dealing with the army in India:—

Sand-fly fever.—In India as a whole the variation in the incidence of sand-fly fever shows little change over a series of years; but when individual stations or small areas are considered, very remarkable differences are seen, and with the exception of the effect of the presence or absence of 'salted' individuals, knowledge of the causes of these variations is very slight. Thus the ratio per 1,000 in Landi Kotal increased from 227.3 to 394.5 per 1,000, ascribed, probably quite correctly, to the presence of an 'unsalted' British infantry unit, but, in spite of this local increase, the incidence in the whole Northern Command fell from 123.6 to 72.1 per 1,000, a decrease in which all the plains stations shared. On the other hand, there was an increase of nearly 100 per cent in the plains stations of Lucknow and Meerut Districts.

In India, sand-fly fever is a disease of the comparatively hot and arid areas of the North-West Frontier and Northern Punjab, and in the plains the disease shows a tendency to occur in two waves, the first in April/May and the second in July/August. The second wave may be due to the return of susceptible individuals from the hills, but it is possible that climatic conditions are a determining factor. A study of the monthly figures of incidence gave no correlation with either rainfall or mean relative humidity, but a mean 8.0 a.m. temperature of over 70°F. and under 90°F. was associated with an increased incidence of the disease. Monthly figures, however, are too wide for the study of a disease with such a short incubation period and of such short duration. The question is further complicated by the admitted difficulty of diagnosis, particularly of cases occurring at the beginning or end of the epidemic season, which are very apt to be confused with influenza or malaria.

No really effective methods of prevention have been devised. Repellants such as P.C. oil are of limited value owing to their evanescent effect, while sand-fly nets are much too airless for use in a tropical climate. Spraying with insecticides will reduce the incidence of the disease, especially in small barrack rooms whose occupants have no night duties to perform. This, however, is an expensive measure and not applicable under field conditions.

Enteric fevers.—Of the 493 cases occurring among British and Indian troops, 254, or just over half, were diagnosed by the isolation of the specific organism, the remainder being classified as enteric group.

Blood culture remains the most certain method of diagnosis, although it missed 1 in 5 cases. Of the 48 cases which gave negative results, 95 blood cultures were performed; 4 in 3 cases, 3 in 9 cases, 2 in 20 cases, and 1 in 16 cases. In all but two cases the first culture was taken before the seventh day of the disease. Of the 195 positive cases, 153 were diagnosed on the first culture, 36 on the second, 5 on the fourth, and 1 on the fifth.

The results of faeces culture, as has been previously pointed out, do not represent the full possibilities of this method of diagnosis, for cases which have positive blood cultures in the early stages of the disease are considered to be diagnosed and have no faeces examinations carried out until convalescence. Even so, the results are disappointing.

A point worthy of note is that occasionally the organism is discovered in the stools on one or two occasions long after clinical convalescence has been established. This occurred in no fewer than 9 of the cases, i.e., 3.7 per cent. It is possible that this may be due to the shedding of material from healing ulcers, although no microscopic evidence of this has been noted.

The results of urine culture, like those of faeces culture, are not entirely representative. In this case, however, there are no difficulties of isolation to contend with, and it seems fairly certain that only a small proportion of cases in India excrete enterica organisms in their urine.

Dysentery.—There was a considerable increase in the number of dysentery admissions for the year, more than can be accounted for by the drop in the figures for diarrhoea and colitis. While this may be in part due to the fact that the troops are becoming more alive to the necessity of reporting sick whenever symptoms of diarrhoea manifest themselves, there is no doubt that it is also in part a true increase.

The figure for bacillary dysentery is almost identical with that of 1930. Protozoal dysentery has fallen by 2.7 per cent, and there has been a corresponding rise in clinical dysentery.

Treatment of dysentery has been along the same lines as in previous years. Polyvalent high potency (double strength) anti-dysenteric serum 'Hoechst' has been tried and very favourably reported on, and arrangements have been made to maintain a stock of this serum.

On the whole the cases have been of a mild type and have responded readily to treatment. Among the 1,593 cases occurring among British troops, one death occurred in a case diagnosed clinical dysentery.

Malaria.—The number of chronic relapsing cases sent to the Malaria Treatment Centre, Kasauli, has been declining of late years, and in 1931 only 126 cases arrived, compared with 241 in 1930. This marked falling off in numbers has been ascribed to the more general use of plasmochin, which is now included in the official list of drugs.

The main investigation both in the treatment centre and in the large hospitals has been directed towards determining the minimum effective dose of plasmochin. It is now accepted that 0.03 gramme of plasmochin plus 20 grains of quinine daily for twenty-one days will reduce the relapse rate to the neighbourhood of 5 per cent. In Poona 325 cases were treated with

0.03 gramme for ten days, followed by 0.02 gramme for eleven days, plus 20 grains of quinine daily. The relapse rate was only 2.8 per cent. At Kasauli two new courses of treatment were tried, viz:—

Plasmochin 0.01 gramme plus 20 grains quinine daily for twenty-one days—10 cases, and plasmochin 0.03 gramme plus 20 grains quinine for fourteen days—9 cases.

The numbers are very few, but so far no relapses have occurred after an average observation period of ten weeks.

Short courses of six- and ten-day treatments were tried in Quetta, but the results were not so favourable. Various observers have noted that retention in hospital for ten days has a beneficial effect in preventing relapses.

During the year a quantity of the new synthetic preparation, atebrin, was obtained. The producers claim that this drug acts equally promptly on the schizonts of both *P. vivax* and *P. falciparum* and cures the attack in five to seven days with 0.1 gramme three times a day. The drug apparently accumulates and continues to be excreted for varying periods up to twenty days after cessation of treatment. So far very few cases have been treated, but the results to date indicate that atebrin will cure the attack. If this drug proves effective in preventing relapses, then a combination of atebrin for five to seven days, with a short course of plasmochin during convalescence, holds out the promise of a cure, not merely of the individual attack, but of the infection. This would lead to the eradication of gametocyte carriers, and such a cure would be of inestimable benefit to the army.

On the result of James's experiments in London, it was decided to try plasmochin prophylactically during the operations in Burma. The earlier trials were promising, but the final results were not so satisfactory. It is considered that the favourable results in the early stages were due to the curative action of the drug rather than to any definite prophylactic effect.

ABSTRACTED FROM THE NINETEENTH ANNUAL REPORT FOR THE OPHTHALMIC SECTION OF THE DEPARTMENT OF PUBLIC HEALTH: MINISTRY OF THE INTERIOR, EGYPT, 1931

This report opens with a series of thirty-eight of the forty-nine photographs which have been opened in Egypt between the years 1904 and 1932. Some of these hospitals are large imposing buildings and a glance at the photographs gives perhaps a better idea of the extent of ophthalmic work in Egypt than many pages of a written report would do.

The amount of work done is shown in the following table:—

	1930	1931	Increase in 1931
			Per cent
New patients ..	526,406	634,088	20
In-patients ..	20,136	22,188	10
Operations ..	209,662	220,823	5
Out-patients attendances.	4,350,062	5,023,175	15

ABSTRACTED FROM THE REPORT OF THE HAFKINE INSTITUTE FOR THE YEAR 1931. BOMBAY

The institute continued to function during the year as (a) the centre for manufacture of plague vaccine for the whole of India, (b) the provincial bacteriological laboratory for the Bombay Presidency, (c) the centre for manufacture of antirabic vaccine for Bombay

Presidency and adjoining areas, and treatment centre for Bombay city, and, in addition, carried out research work on plague and other subjects as in former years, largely with the assistance of the Indian Research Fund Association.

Plague work.—The manufacture of the vaccine has, as in former years, constituted the main activity of the institute. The demands for vaccine continue to be high in proportion to the incidence of plague mortality, and the slight rise in plague during the year over the number of cases occurring during 1930 was reflected in an increase in issues. It has been shown in previous reports that a regular increase in demand in relation to cases occurring has continued in successive years, and the proportion of issues in the present year has been 31 doses of vaccine for each plague death registered. During recent years the institution of a fresh experimental investigation into the vaccine and its properties, and into the effect of each procedure employed in preparation has resulted in undoubted improvements. Experimental evidence has shown an increase in its immunizing value as the result of the use of revised methods. Such statistics as are available as to the protective value of vaccine prepared in recent years as compared with older results also suggests a marked increase in potency.

The methods introduced by Dr. Gore for the preparation of pure strains of *B. pestis* from passage animals for seed purposes have been found to be fully effective. The differential methods for determination of purity which are now used have ensured that the losses of vaccine under preparation which formerly occurred due to the use of impure seed could be completely avoided.

The relationship of virulence to potency and toxicity to potency have been studied and also the effect of the period of incubation, temperature of incubation, reaction and composition of medium on the immunizing value of the vaccine. The question of a technique for biological standardization of the vaccine has been the subject of further study. A prolonged series of experiments with different brews of vaccine has given consistent results, but at intervals difficulties have been experienced due to changes in virulence of the passage strain of *B. pestis*. It is hoped that when this difficulty can be overcome the method of testing will afford a reliable means of ascertaining the value of successive brews and of comparing the potency of vaccines prepared by variations in technique by entirely different methods. The technique has been applied to the comparison of the relative value of Haffkine's vaccine to agar-grown and 'derived' vaccines prepared by other laboratories. The results of some of these tests are given in the research section of this report and only one vaccine has been found to compare with the Haffkine vaccine, this being a vaccine of high bacterial content and toxicity. Chemical studies of the changes occurring in the vaccine during the period of incubation have been carried out with the object of ascertaining the probable immunizing fraction.

Many of the sera prepared have been of high potency as tested on experimental animals and a trial on a short series of human cases has given very promising results.

The pharmacological unit.—The principal investigation carried out during the year was in connection with scorpion stings. The properties of the scorpion venom were very fully studied. The toxicity of the venom of various species was determined in relation to body weight and the conclusion arrived at that a scorpion sting could in no case be fatal to a normal human being. The various traditional Indian plant remedies for scorpion bite were investigated and found to be without value.

The biochemical unit.—An extensive investigation was undertaken into the normal standards of chemical constituents of the blood of adult Indians in order to establish a basis for a future investigation into the changes occurring in the blood in kidney and other diseases in persons whose dietary and, in particular,

whose protein intake differs widely from that used in western countries for which standards have been established.

The antirabic department.—The number of cases of dog-bite receiving prophylactic treatment has, as in former years, shown a progressive increase. The total dealt with at the institute rose to 1,061 with a mortality of 0.28 per cent which compares very favourably with that of other institutes in India. In addition to these cases 5,998 were treated at out-centres. The results for the last two years since the introduction of the use of the Paris strain of fixed virus and graded courses of treatment according to the assessment of risk have been the best recorded. A corresponding improvement has not taken place in regard to cases treated at out-centres. The majority of the institute cases are from Bombay city itself and the early stage at which cases attend for treatment and the thorough immediate disinfection measures adopted may be responsible in some degree for the better results obtained. The first case of a 'paralytic accident' amongst those treated with vaccine prepared at this institute was recorded during this year. The case fortunately ended in complete recovery.

ABSTRACTED FROM THE DIRECTOR'S REPORT OF THE LEAGUE OF NATIONS HEALTH ORGANIZATION ON THE WORK OF THE EASTERN BUREAU FOR THE YEAR 1932

ADVISORY COUNCIL

The year under review was the only one since the Bureau was established in which no meeting of the Advisory Council took place.

The greater part of the report consists of detailed accounts of health conditions in the chief ports of the East during the year under review and is therefore only of historical interest. The organization of the Bureau whereby all countries in the Eastern hemisphere are advised every week of the state of chief epidemic diseases everywhere in the area is fully described and on account of its importance it has been fully abstracted below.

EPIDEMIOLOGICAL INTELLIGENCE

This service constitutes the main function of the Bureau. It has been steadily built up in the eight years that have elapsed since the Bureau commenced to function and consists of three divisions for the reception, collation, and distribution of information.

Reception.—The reception service covers the whole of the Eastern arena, extending on the West as far North as Alexandria and Syria; on the South-West to the Union of South Africa; on the North-East to Vladivostok; on the South-East to Australia and New Zealand, and as far into the Pacific as the Hawaiian Islands. From all the Health Administrations of this extensive area communications are received regularly by cable or by post.

Cables.—The cable service comprises an emergency one, under which immediate information is forwarded concerning the first appearance of plague, cholera, small-pox or other communicable disease in epidemic form in the ports, and a regular one comprising a routine weekly cable giving the position in regard to these diseases each week in the ports and provinces.

The outstanding feature under this section for the year has been the taking over by the National Quarantine Service of China, on and from 6th April, of the quarantine services of Chinwangtao, Tientsin, Tangku and Taku. From the headquarters of this service at Shanghai returns are now regularly received concerning the existence of infectious disease in Hankow, Nanking, Shanghai, Amoy, Swatow, Canton, Tientsin, Tangku and Taku, Antung, Newchwang and Harbin. Unfortunately there is not the same degree of accuracy in the returns from each of these ports, and particularly does this apply to Swatow, where the quarantine administration is dependent on the Health Department

for information. This lack of accuracy is all the more to be regretted because unofficial reports arrive at the Bureau from time to time which suggest that the health of the port may be less satisfactory than official communications indicate. Swatow has a considerable trade with ports of other countries, and owing to the uncertainty which exists, quarantine measures which may or may not be in conformity with actual requirements are liable to be taken by these ports.

From the Head Office of the Netherlands East Indies Public Health Service, Batavia, information has been received that the number of N.E.I. ports from which communications are received, and in regard to which returns are sent to the Bureau, is now twenty-six (26).

Number of ports.—The number of ports in regard to which information is now received by cable amounts to one hundred and sixty-three (163).

Postal.—By post supplementary information is received weekly confirming the routine cable, giving further information in regard to the state of communicable diseases in the provinces and districts, as well as information as to meteorological conditions, birth and death rates, mortality rates from certain diseases, particulars regarding rat destruction operations and measures taken against infected ports. In addition to weekly information, four-weekly postal returns are received from a number of Health Administrations, while annual reports from the greater number of these also come to hand.

CO-ORDINATION OF INFORMATION

The information received in the routine cables refers to the condition which existed during the preceding week ending at midnight each Saturday. This information begins to arrive at the Bureau on Monday, but it is not until Wednesday morning that the bulk of the returns are to hand. In the case of certain countries, particularly British India, owing to the number of provinces to which the returns relate and the consequent delay in receiving information at Delhi, it is not until Thursday morning that all returns are finally received. During these four days the information is sorted out and arranged for distribution. This comprises decoding of separate cables and combining their contents into comprehensive general cables and coding them for distribution. The material contained in the weekly postal returns is at the same time into the form in which it can be used in the published by the Bureau.

DISTRIBUTION SERVICE

The methods of distribution are wireless transmission, telegraphic communication and postal circulation of a The information for the week is transmitted by cable each Thursday morning to Saigon where, through the courtesy of the Government, it is emitted from the powerful wireless station each Friday morning in code. This message is picked up either directly or indirectly throughout the whole of the area from which information is received. The East coast of Africa receives the message indirectly through the intermediary of the station at Tananarive, which picks it up and re-transmits it each Saturday morning. The Saigon message is also picked up by the Malabar Station, which transmits it in code each Saturday morning both on long and short wave. In addition, certain Administrations summarize the decoded message and re-transmit it in clear in an abbreviated form. This is done from Hongkong, Karachi, Madras, Sandakan, Shanghai and Tokio weekly, and from Malabar daily.

The most noticeable advance in connection with the wireless transmission would be the addition of a clear message from Saigon as well as the code message. Through the courtesy of the Government of Indo-China it appears likely that this will be possible in the very near future. The proposal is that the message should be transmitted in code followed by transmission in clear in the English language on short wave. The translation from code to clear message will be carried out by arrangement with the Inspector-General of Medical and

Sanitary Services at Hanoi by the local Director of Health at Saigon. This will meet the request of many Eastern countries for transmission in clear instead of in code, and at the same time allow those Administrations which still desire a code message to receive it.

Quarantine notifications.—In addition to notifying the incidence of disease, one feature in the wireless messages is the inclusion of information concerning the measures taken by particular ports to protect themselves against infection which exists in other ports. Each week these notifications are brought up to date, and quarantine procedure can now be based on an actual knowledge of the diseases which have to be guarded against.

Transmission in clear.—To meet the requirements of ships' masters who desire to know the prevalence of major communicable diseases in the ports with which they are trading, a message in clear is transmitted daily, by the courtesy of N.E.I. Government, from Malabar. That this message fulfils a need is shown by the fact that it is regularly picked up by steamships of different flags. A proposal was put before the recent Conference at Madrid which had under consideration the revision of the International Radio-telegraphic Convention of Washington, 1927, that the Bureau's messages should be classed for the East as 'Special Services' under the Convention. This, however, was not approved, and in consequence the full value of the service cannot at present be realized.

During the year only one failure to pick up the Saigon broadcast has been reported, and this was by British India. The reception of this message, which was transmitted on the 23rd December, was interfered with by atmospherics, but this difficulty was overcome by picking up the clear broadcast from Malabar.

TELEGRAPHIC COMMUNICATION

Emergency cables.—Cables notifying the appearance of 'first cases' are immediately despatched to Geneva and from there to Paris. In addition, this information is immediately re-transmitted by cable to all ports having trade relations with those in which these 'first cases' have appeared. This gives the health authority warning of the potential danger, and enables steps to be taken in advance to meet it.

Routine cables.—Twice a week, namely, on Wednesdays and Thursdays, cables are forwarded to Geneva, and from Geneva to the Office International, Paris, which contain a summary of all the information received for the previous week. The despatch of these cables complies not only with the desire of Geneva for information for distribution, but also with the obligations which the Bureau has undertaken as an agent for the Office International, Paris. These cables arrive in Europe in time for their contents to be included in the Weekly Record published at Geneva by the Health Organization.

Cablegrams are still required for despatch of information to certain ports which are unable to pick up wireless messages, or are only able to pick up a re-transmitted abbreviated summary of These ports are Vladivostok, Canton, Aden and Seychelles.

Infected ships.—Cabled information that a ship infected by one or other of these diseases is on its way to a particular port is of great value, both to the Port Health Authority and the agents of the ship. Every endeavour is made to obtain information at the earliest possible moment regarding the next port of call of any infected ship, as well as the nature and extent of the infection and the measures which have been taken to control it. This information is transmitted to the next port of call with the result that duplication of precautionary measures need not occur, and the Port Health Officer is enabled to apply only such measures as are necessary to protect his population.

Weekly fasciculus.—In order to supplement the information transmitted via wireless and cables, a Fasciculus is published each week which confirms the news sent by the other methods and includes a great

deal of additional information relating to the state of countries and provinces as regards the existence of other infectious diseases. This Fasciculus also supplies information regarding the movement of population between various ports, both regular movement and movement at times of pilgrimages. The notification of quarantine measures applied against various ports is brought up to date and a list is given showing those ports which have been infected with plague, cholera and smallpox during the preceding 12 months, together with the date of the last infection.

The Fasciculus is now distributed directly from the Bureau to a number of Health Officers in the Federated Malay States who previously received their copies through the intermediary of the headquarters of their Department in Kuala Lumpur. Additional copies of the Fasciculus are this year being required for distribution to a greater number of institutions and health workers in Japan who have requested to be put on the mailing list, and to Medical Officers of estates in Malaya.

By the use of these three methods it is possible to ensure that every public health administration in the East knows within a few hours of the occurrence of any fresh outbreak of plague, cholera and smallpox in ports with which it has direct trade communications. It is possible to ensure further that every health administration knows the state of health of each one of the 163 ports from which information is received, up to the previous Saturday night, and at a later period that each health administration is possessed of detailed information regarding the state of health of countries in the East, as well as the state of health of the ports of such countries.

MALARIA COURSES

Arising out of Prof. Ciucea's visit, when tentative discussions took place regarding the establishment of international malaria courses in the East, arrangements were come to with the Medical School at Singapore whereby the latter was to carry out the technical work, if it were decided by the League to establish these courses at Singapore. The proposal has now been approved, and preliminary arrangements are in hand for the first of these courses to commence on 30th April, 1934. It is proposed that the League should bear the expense of five fellowships, which will be offered to administrations which are prepared to send an additional member to the course at their own expense. It is hoped that there will also be a number of entries from Eastern Governments and from practising physicians.

The League proposes that the theoretical work should be carried out at Singapore and the practical work in several Eastern countries, the arrangement being that members of the course should have the opportunity to study field work in a country other than the one in which they are themselves working. The League also proposes to bring two experts each year from overseas to assist in the course.

The estimated cost per annum, namely, 38,000 Swiss francs, will be borne by the Budget of the Health Organization.

ABSTRACTED FROM THE REPORT OF THE BOMBAY SOCIAL HYGIENE COUNCIL FROM JULY 1931 TO DECEMBER 1932

THIS report covers the half-year ending December 1932 during which period the Council entered in its sixth year of existence. But the formation of this council and its affiliation with the British Social Hygiene Council in 1926 does not mark the beginning of organized effort in Bombay to deal with venereal disease, because the present body arose out of the League for combating Venereal Disease which had been in existence since 1917.

SEAMEN'S WELFARE IN PORTS

The prevalence of venereal diseases in the mercantile marine is considerable. The continued change of venue

of its members and the temptations for misconduct existing in most seaport towns are factors that loom large in the life of a seaman. Seamen's welfare in ports is therefore at once an international problem which can only be solved by the maintenance of treatment facilities for those who have been infected and the provision of such measures as will tend to prevent cases of infection at the seaport. The importance of both these aspects is emphasized by the fact that in 1924 an International Convention was instrumentalized through the Belgian Government under the title of Belgian Agreement by which the contracting governments 'agreed to create and maintain in each of their principal ports, whether on river or sea, venereological services open to all merchants, seamen or boatmen without distinction of nationality'. Under this scheme a seafarer obtains treatment at every port of call. Any person treated at any of these international centres receives a *continuation case book* in which the medical officers of the various clinics visited, enter details of diagnosis and treatment and the case is thus followed up.

Over 20 nations have adhered to the terms of the Belgian Agreement and have taken definite action on it. But the Government of India, though approving of the principle underlying the scheme, has not accepted it, and India therefore remains an international offender..... However, within the British Empire, while Great Britain, Australia, Canada, the Irish Free State and New Zealand are signatories to the Agreement, many of the colonies, mandated territories and protectorates provide good facilities for the diagnosis and treatment of venereal diseases in seamen though they have not accepted the Agreement and our position in Bombay is evidently analogous to that of the latter countries.

The port of Bombay is one of the largest in India. It is visited by European, American and Asiatic ships. The total number of ships visiting the port each year is 3,951 and the average crew about 60 per ship, so that roughly 240,000 members of the mercantile marine visit the harbour each year. There is besides a considerable number of native craft estimated at about 10,000.

It is imperative therefore that we should organize a voluntary anti-venereal service for the seamen. It would lessen the infection among our floating population, while it would lessen the risk of their infecting the civil population. Above all it would tend towards the fulfilment of a duty to the world nations who have a right to expect us to treat their men as they treat ours. The Bombay Social Hygiene Council has therefore striven to promote those measures which fall in with the spirit of the Belgian Agreement and which will make Bombay a voluntary contributor to the international scheme. During the year under review we have met with a certain amount of success in our efforts.

GOVERNMENT V. D. CLINICS

Facilities exist and more are being brought into existence in government and municipal clinics for the treatment of seamen. As an additional measure of more handy relief we suggested to the Government of India the establishment of a centre in the vicinity of the docks. In reply they have informed us that since the St. George's and the Gokuldas' Hospitals are not very far away from the harbour a scheme is under consideration by the local government for providing special arrangements at these hospitals for the treatment of seamen suffering from venereal diseases. It is gratifying to note that government are moving in the matter.

PORT TRUST DISPENSARY

In accordance with a resolution passed at the general meeting of the council held in August 1929, the Chairman of the Bombay Port Trust was requested to consider the necessity of including modern diagnosis and treatment of venereal diseases in the scheme of a

new dispensary that the trust was contemplating. We received a reply that the matter was receiving attention but as a result of further correspondence we have now been informed that the scheme has been postponed for financial reasons and that the Board is of opinion that when it comes to fruition treatment of V. D. cases should be restricted to the employees of the trust for whose benefit the dispensary existed.

We have no grounds for criticizing the decision of the board. But till such time as a Port Sanitary Authority comes into existence, we hope the Bombay Port Trust will re-consider the matter and contribute their quota to the solution of the problem by throwing open the port trust dispensary for the disinfection and treatment of infected seamen.

The seafarer is an agent in the prosperity of the port. Under the Consolidated Act, the Port Trust gives grants to local institutions which promote the welfare of seamen. We suggest that the claim we put forward is urgent and necessitous and we hope the Port Trust will make the necessary provision.

INFORMATION TO SEAMEN

On the suggestion of the Port Officer, Bombay, and at the request of government we undertook the publication of a pamphlet in four languages, English, Gujarati, Urdu and Konkani for the guidance of seamen, pointing out the dangers of venereal diseases and giving particulars of the medical facilities for diagnosis and treatment at the Port of Bombay. These pamphlets were very kindly printed at the expense of government and are now being distributed to seamen by the Port Officer and Shipping Master of the Port of Bombay and by the Secretary, National Seamen of India Institute.

CONTINUATION CARDS

The Surgeon-General with the Government of Bombay and the Executive Health Officer for the city have kindly agreed to provide for *Continuation Case Books* according to the international pattern in the case of seamen patients applying for treatment at the government and municipal clinics. This is a measure which will enable these patients to obtain treatment in continuity at all ports of call as enacted by the Belgian Agreement.

SOLICITATION AT THE DOCKS

The attention of the Government of Bombay was drawn to Question No. 6 of Report III of 1931 of the International Labour Conference on 'Promotion of Seamen's Welfare in Ports' and the council wrote to inquire whether government was of opinion that soliciting and enticing of seamen in the harbour area should be prohibited and if so what steps government proposed to take in the matter. We received a reply to say that the Governor in Council was of opinion that it was desirable to prohibit the soliciting and enticing of seamen in the harbour area but government's information was that there was no actual soliciting in the docks in Bombay. In consultation with the Bombay Vigilance Association it was pointed out to government that while admitting that there may be no obvious solicitation in the docks the fact that women could board certain ships when they arrive in the docks tends to produce the same results as open solicitation. Also apart from the women themselves soliciting there were the victoria drivers who were potential pimps. We have now received a reply from government to say that it is reported that the masters of ships who allow women on board are masters of vessels which are foreign, i.e., neither British nor Indian; that it has to be remembered that many foreigners take a different view of this question and allow women on board their ships not necessarily because they are prostitutes but oftener than not because they are of the same nationality as the ship and possibly because they have friends on board. Under the circumstances it could not be proved that these women go on board on every occasion with the express object of soliciting and in any case the responsibility for preventing access of persons

of this description to a ship rested with the master and not with the police as it was within the power of the former to issue orders for undesirable visitors to be refused admission on board. In order to exercise some sort of check it was necessary to secure the co-operation of the masters of the ships and the government proposed to address the Shipping Master, Bombay, in the matter and to ask for his co-operation. In connection with other solicitation government intimated that their information was that the number of professional pimps who can obtain access to the dock area in Bombay without being detected by the police was negligible and agreed that the licensed drivers of public vehicles were a potential source of pimps.

We are awaiting further communication in this matter regarding the action of the Shipping Master.

RECREATIONAL FACILITIES

The steps taken to reduce the spread of diseases from country to country are, besides the provision of medical facilities, an increase of recreational facilities, shore sleeping accommodation and attention to the social conditions of the ports. Experience gained in the various armies and navies has led to the recognition of the fact that direct relationship exists between recreational facilities and the incidence of venereal diseases. Where counter-attractions exist there is less promiscuity and, consequently, less venereal disease.

The Prince of Wales Seamen's Institute for Europeans is an excellent institution run in connection with the Missions to Seamen and erected on land provided by the port trust. It has been in existence for some years. We welcome the Indian Seamen's Home which was recently constructed also on land provided by the port trust as a memorial to Indian seamen who lost their lives in the war. It is a splendid building designed to accommodate and recreate lascar seamen, and we welcome it all the more because although the need of it had been recognized for many years and a considerable proportion of the required funds was available, no constructive action was taken until the delegates of the British Social Hygiene Council visited Bombay in 1926 and took the matter up with government.

We realize that it is necessary that government should allocate a special playground to the mercantile marine and contemplate reiterating the request made to government by the delegates of the British Social Hygiene Council, that such a provision be made when the Back Bay Reclamation Scheme is completed.

On account of lack of space we regret we are unable to abstract from this report more fully but in addition to the work outlined above the council is engaged in educational propaganda including an exhibition at the national baby and health week association held at different mulls every week, writing articles for insertion in popular vernacular magazines, and courses of lectures to social workers. Owing to their efforts it is hoped that the council will soon have prophylaxis centres at the public hospitals and information regarding these posted up in the public urinals.

It is impossible even to mention all of the many activities of this body of voluntary workers, but perusal of the report shows that they are fully alive to the danger of venereal disease in all its aspects and they are attacking its many problems in the most enlightened manner.

Not the least remarkable fact in this campaign is that the total cost of the work for the year 1932 is only fifty-six rupees fifteen annas which shows this movement is truly honorary, and Bombay is fortunate in the possession of a body of such energetic and public-spirited workers.

ABSTRACTED FROM THE EIGHTH ANNUAL REPORT OF THE PASTEUR INSTITUTE, CALCUTTA, 1931

The total number of patients who attended the institute for treatment and advice during the year was

10,426 as compared with 9,094 during the previous year. This is the highest figure yet obtained. Of this number, 7,761 were given a full course of treatment, 1,737 were given advice only as no treatment was considered necessary in their cases, and 823 patients voluntarily abandoned treatment (absconders). The number fully treated exceeds the previous year's corresponding figure by 803 and the number of absconders by 140. The figure of absconders is very high, there is no control over these cases as most of them are non-indigent and come at their own expense for treatment.

Treatment.—The vaccine used for immunization is prepared by Semple's method from sheep's brain with the Paris Fixed Virus. The strength of the emulsion used is 1 per cent and the dose is—

Licks—5 c.c. daily for 7 days.

Bites—5 c.c. daily for 14 days for all classes of cases.

Results of treatment.—The statistical results are based on the health returns of patients 6 months after completion of treatment. The total percentage of these returns for all cases during the year is 67.9 per cent. Great difficulty has been experienced in tracing the patients at the end of the 6 months' period and numerous replies from district and despatching officers have stated that the patient had left the village and his present whereabouts are not known.

There were 57 deaths from hydrophobia during the year. Of these 14 arrived at the institute after the disease had developed and are excluded from the deaths. Of the remaining 43 deaths, 8 developed the disease during treatment and 7 within 15 days of completing treatment and are regarded as 'Non-failures'. The remaining 28 cases developed the disease after 15 days of completion of treatment and are regarded as 'Failures', giving a total death rate of 0.55 per cent and a failure rate of 0.36 per cent for the year.

There were no deaths among the 254 European cases treated during the year.

Decentralization of treatment.—It has not been possible to issue vaccine to treatment centres owing to the limited accommodation available for the work of this institute. The bottling of vaccine in ampules, which is the only safe method of issuing vaccine to out-stations and treatment centres, cannot be undertaken at present for want of proper accommodation. A scheme for the reorganization of the institute and the provision of more accommodation so as to start a bottling section has been submitted to government and should it be accepted, the bottling section will be opened and the vaccine issued to treatment centres. This will relieve the present congestion which exists besides greatly reducing the total cost of the upkeep of the institute.

Correspondence

MODI'S MEDICAL JURISPRUDENCE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With reference to the review of his book which appears in the June number of the *Gazette*, Dr. Modi has made the following comments:—

'The tables re. the ages at which the epiphyyses of long bones unite, etc., were adopted by the author in consultation with the Professor of Anatomy of the King George's Medical College, Lucknow, and the Radiologist, King George's Hospital, Lucknow, whose investigations do not concur with those of Dr. Galstaun. They were aware of his article in the *Indian Medical Gazette*.'

Re. the remarks of the reviewer about the treatment of arsenic poisoning by sodium thiosulphate his attention is invited to the following paragraph on p. 681 of the book under review:

'George W. Lawson, W. P. Jackson and George S. Cattanaeh recommend the intravenous injection of 7½ grains of sodium thiosulphate in 10 per cent solution. They tried it in 28 cases of poisoning by arsenic after the stomach was washed out with warm water. Of these 15 recovered and 13 died from 6 hours to 13 days.'

Yours, etc.,

BUTTERWORTH & CO. (INDIA), LTD.

CALCUTTA,
4th July, 1933.

VACCINATION AGAINST SMALLPOX

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the letter of 'C. L. B.', Bombay, published on page 359 of your issue of June 1933 under the heading 'Vaccination against Smallpox', it is stated by him:—'I object to the circular drill seemingly approved in the last paragraph of Colonel Stewart's note' and further says:—'In highly skilled hands the drill may possibly be successful, but I submit that it can never be as good as a cutting edge or point'. I do not agree with this view, and would offer below a few remarks on the subject.

There is no doubt that the vaccination operation is a trivial one, but all the same it requires a certain amount of skill and practical experience to have it done as it should be to obtain satisfactory results. It is seen that a considerable number of failures or cases reported as 'unsuccessful' or even 'insusceptible' in the hands of one vaccinator are found to show quite a 'successful take' in the hands of another vaccinator, this, of course, irrespective of the quality or potency of the lymph used. The technique of this little operation varies considerably, not only throughout India but also throughout the world. Each country and even each individual seem to adopt his own method considering that to be the best one. Linear incisions with an ordinary scalpel or other cutting-edge vaccinating lancet are the ones generally adopted in Europe. Dr. Force in America used his drill method, which consists in applying vaccine lymph to a two-millimetre circle of derma exposed by removing the epidermis by means of the rotatory motion of a small drill held perpendicularly to the tightly-drawn skin. On the other hand Leake of the United States Public Health Service has adopted the 'Acupuncture' or multiple puncture method with remarkable success. It is interesting to note that both these methods are officially approved and recommended under the New York Regulations. The 'acupuncture' method however is being now generally recognized as about the best. Canada also officially recommends this method to all its vaccinators. In this Presidency however a method recommended to all public vaccinators is of a circular incision by means of a rotatory lancet devised and manufactured in this institute and supplied to all public vaccinators. It consists of a circular disc four millimetres in diameter provided with five tiny conical-shaped needle points. Four of these are on the periphery of the disc and one very slightly longer than the others in the centre. The other end of the lancet is provided with a tiny scoop for placing a drop of lymph on the area to be vaccinated. Through the drop of lymph applied on the skin, the disc end of the lancet, held perpendicularly, is gently pressed and rotated. This, unlike Force's drill method, results in only breaking the skin in a circular incision of just

sufficient depth. Very little oozing of blood is noticed. The central needle point does not as a rule break the skin. Its main function is to fix the lancet and it, being slightly longer than the peripheral ones, serves to press the skin down and thus stretching it helps to cut it more easily by the latter. It will be obvious therefore that such a lancet is absolutely safe in the hands of public vaccinators in India, or at least in this Presidency, who are not qualified medical men. With this lancet they can cut the skin so far and no further. The same could not be said about a knife edge in their hands for vaccination purposes. The knife may be second to none in the hands of medical men, but I do not agree with 'C. L. B.' that it is better than our knuckles in the hands of our vaccinators. This would be best judged by the results of 748,530 primary vaccinations done by the public vaccinators in this Presidency, including Sind, during the year just ended. It is to be particularly noted that all these vaccination operations were done by Belgaum Vaccine Institute pattern of rotatory lancet. The case success rate of these vaccinations is 99.94 per cent, and the insertion success

rate 99.28 per cent. These figures or results will speak for themselves and require no further comments.

In this connection it would be interesting to note the opinion of the International Committee on Smallpox and Vaccination of the Health Organization of the League of Nations in their Report of August 1928. They state:—'The best lymph may have the most different results, according to the manner in which it is used. Next to individual susceptibility, the most important factor is vaccination technique. The Committee does not consider it desirable or even within its province to declare that any particular defined method of vaccination should be exclusively employed by vaccinators in all countries'.

Yours, etc.,
J. L. PINTO, D.P.H.,
Director.

VACCINE INSTITUTE,
BELGAUM,
12th July, 1933.

Service Notes

APPOINTMENTS AND TRANSFERS

THE Indian Research Fund Association has elected Major-General J. D. Graham, C.B., C.I.E., R.H.S., Public Health Commissioner with the Government of India, to be its representative on the Imperial Council of Agricultural Research, with effect from the 18th March, 1933, *vice* Lieutenant-Colonel A. J. H. Russell, C.B.E.

To be Honorary Surgeon

Colonel J. P. Cameron, C.S.I., C.I.E., *vice* Major-General W. C. H. Forster, C.I.E., retired. Dated 19th July, 1933.

Colonel H. R. Nutt, V.H.S., Officiating Surgeon-General with the Government of Bombay, is confirmed in that appointment, with effect from the 20th July, 1933.

The services of Lieutenant-Colonel F. A. Barker, O.B.E., Inspector-General of Prisons, Punjab, have been replaced at the disposal of the Government of the Punjab, with effect from the afternoon of the 29th June, 1933.

The Viceroy and Governor-General has been pleased to confirm Major W. R. Stewart in his appointment of Surgeon to His Excellency, with effect from the 18th July, 1933.

On return from leave, Major S. D. S. Greval, an officer of the Medical Research Department is appointed to officiate as Assistant Director, Central Research Institute, Kasauli, *vice* Major Maitra, with effect from the date on which he assumes charge of his duties.

The services of Captain T. J. Davidson are placed temporarily at the disposal of the Government of Burma, with effect from the date on which he assumes charge of his duties.

Captain J. C. Drummond, Civil Surgeon, Midnapore, is posted at the Medical College Hospitals, Calcutta, until further orders.

Captain R. Linton is appointed as Civil Surgeon, Midnapore, *vice* Captain J. C. Drummond, I.M.S.

Subject to His Majesty's approval the undermentioned I.M.S. officers are confirmed in the following order on passing the necessary courses of instructions:

Captains

J. H. Crawford; G. R. M. Apsey.

Lieutenants

J. D. Grant, M.B.
T. E. Palmer, M.B.
W. H. G. Reed, M.A.
W. J. Poole, M.B.
C. J. H. Brink, M.B.

The dates of seniority of the undermentioned Lieutenants (on probation) are antedated to 24th April, 1932—

H. A. Ledgard.
T. F. O'Donnell.
Said Ahmad.
C. C. Kapila.
J. White.

PROMOTIONS

Lieutenant-Colonel to be Colonel

A. H. Proctor, D.S.O., V.H.S. Dated 20th July, 1933, with seniority 1st March, 1928.

Majors to be Lieutenant-Colonels

N. M. Mehta. Dated 26th July, 1933.
G. H. Mahony. Dated 31st July, 1933.
G. Corell. Dated 31st July, 1933.
W. R. Stewart. Dated 31st July, 1933.
H. Chaud, M.C. Dated 31st July, 1933.
V. Mahadevan. Dated 31st July, 1933.
A. C. L. O'S. Bilderbeck. Dated 31st July, 1933.
J. W. Vanreenen. Dated 31st July, 1933.
M. Das, M.C. Dated 31st July, 1933.
J. M. R. Hennessy. Dated 31st July, 1933.
H. H. Brown. Dated 31st July, 1933.
C. H. N. Baker, M.C. Dated 31st July, 1933.
K. R. Rao. Dated 31st July, 1933.

The promotion of Major A. J. D'Souza, M.C., I.M.S., to the rank of Major is antedated to 5th May, 1926.

Captain to be Major

R. McRobert, M.B., Ch.B. Dated the 10th June, 1933.

Captain (on probation) to be Major (on probation)

W. Aitchison, M.C. Dated 20th December, 1932.
(Previous notification on the subject is hereby cancelled.)

LEAVE

Major G. C. Maitra, Assistant Director, Central Research Institute, Kasauli, is granted leave for 8 months, with effect from the 1st August, 1933, or the date from which he may avail himself of it.

RETIREMENT

Lieutenant-Colonel H. A. H. Robson retires from the 1st June, 1933.

RELINQUISHMENT

Captain (on probation) E. O'Reilly relinquishes his probationary appointment, 20th May, 1933.

Notes

A NEW ABDOMINAL RETRACTOR

This single retractor has been designed for use in operations on the lumbar sympathetic ganglia. It consists of a long, broad blade with a flat, lower margin rounded at the edges, and attached to a shaft at right angles. The handle of the retractor makes an angle of 10 degrees from the vertical at its attachment to the shaft, and is faceted for the reception of the thumb. This angulation is an advantage. When the handle is held vertically, the lower margin of the retractor is inclined

outwards, thus exposing the more deeply lying structures with the minimum amount of pressure on the overlying coils of bowel. At the same time, the hands of the assistant are well away from the wound, and not above it, as they would be were the handle attached at right angles.

R. BROOKE, M.S.

MURANO GLASS

PROFESSORS of laboratories will be interested to know that the well-known Italian factory of Christalleria Murano, Venice, are now represented in India by Messrs. Ezra Brothers, Ruston Buildings, Churchgate Street, Fort, Bombay.

The main qualities of glass manufactured by this factory are:—

(1) *Murano Tenax Glass Tubings*.—This represents neutral glass (hard glass) tubings to be used exclusively for manufacturing ampoules and vials.

(2) *Murano X Glass* is common glass (soft glass) tubings used for manufacturing laboratory apparatus.

(3) *Murano 1922 N Glass*.—It is a neutral heat-resisting glass used for manufacturing laboratory glass. It may be mentioned that the glass has a thermal resistance of 175° Centigrade, the pH constant at 7.1, and its added advantage over the Jena glass is its greater elasticity.

OPERATING THEATRE LIGHTING

THE operating-theatre light fitting is one of the most important items of present-day hospital equipment.

Modern surgery requires adequate lighting, and the selection of a suitable fitting should be carefully made to ensure that the surgeon may work with the maximum of comfort and efficiency. Some form of shadowless lighting has become an essential detail of an up-to-date theatre.

There are many points to consider in the selection of a light fitting and attention is drawn below to some of the important features of G. E. C. operating theatre fittings:

High Light Intensity.—Over 500 feet candles is obtained over a 12-inch circle with a 200 watt OSRAM general service lamp.

Elimination of Shadow.—Light distribution and diffusion of beam ensure minimum of shadow.

Minimum of Heat.—Due to the opaque bottom of the fitting and the hollow cone of light produced, the neck and head of the surgeon are in an area free from direct light and heat.

Colour Correction.—Spectral quality of the light is unaltered. White corrected glass is used for all transmitting and reflecting surfaces throughout the fitting.

Emergency Illumination.—Incorporated in the fitting itself and possessing generally the same characteristics as the main illumination.

Low Running Cost.—No complicated lens system is employed. Standard OSRAM lamps which are inexpensive and easily obtainable are used. Five hours lighting for 1 unit of electricity.

Easy Maintenance.—Quickly removable top and counterweight inspection cover give instant access to lamps, working parts and wiring.

Ease of Cleaning.—The fitting may be easily and quickly cleaned from the theatre floor.

Ease of Adjustment.—Positive in action, the universal adjustment enables light to be directed in any direction at the required angle.

Simplicity of Installation.—Fittings are wired before despatch and have only to be fixed to ceiling and connected to the hospital supply.

Manufacture.—Made in England by the G. E. C. with the best quality British materials throughout.

Price.—Produced at the lowest figure consistent with quality and efficiency.

OIL-SOLUBLE BISMUTH

'STABISMOL' is a solution of a new oil-soluble bismuth compound which has been discovered and manufactured by Boots Pure Drug Co., Ltd. The formula of the compound is bismuth α -carboxy-cyclo-hexanyl acetate.

The drug is supplied in solution in olive oil, and 1 c.cm. of the solution contains 0.1 gramme of bismuth metal. The advantages claimed for this preparation are that it is less painful on injection and more rapidly absorbed than are aqueous suspensions of bismuth salts or of bismuth metal. The superior rate of absorption has been demonstrated by x-ray photographs. Pharmacological experiments have proved the non-toxicity of the compound, and the purity and sterility of the preparation is controlled by analytical and bacteriological tests. The dosage recommended is 2 c.cm. solution (0.2 gramme bismuth metal) weekly.

Messrs. Boots have prepared an interesting brochure which gives full details of the properties of the drug and its mode of administration, and also gives an outline of soluble courses of combined arsenical and bismuth therapy for various types of syphilitic infection. The introduction of bismuth by Sazeras and Levaditi has proved a valuable advance in the therapy of syphilis, but there has been considerable difficulty in finding a satisfactory preparation of this metal. Preparations which form aqueous suspensions are very slowly absorbed, whilst those given in aqueous solution are painful and have often proved to be unduly toxic. This new oil-soluble preparation ought, therefore, to prove a valuable advance in bismuth therapy.

(The British Medical Journal, Vol. I, p. 1011.)

FERRADOL

(A VALUABLE TONIC)

FERRADOL is a new vitamin preparation containing both manganese and iron in a very palatable and diastatically active malt vehicle which Messrs. Parke, Davis and Co. have just introduced. The vitamins A, B and D are all represented in generous quantity in this formula. The vitamin A content of Ferradol is obtained by the inclusion of halibut liver oil which is of such high potency that the small quantity required does not impair the pleasant flavour of this preparation. Vitamin B value is provided by the content, per ounce, of 25 grains of concentrated biologically standardized vitamin B extract from wheat germ and Irradol has been included in sufficient amount to assure a vitamin-D potency of 5D.

Thus Ferradol provides the fat soluble vitamins A and D in larger amounts than a high grade cod-liver oil, the growth-stimulating vitamin B in sufficient quantity, the anti-anæmic effects of iron and manganese and the nutritive and diastatic value of malt.

The malt extract used in Ferradol is nutritious and is an aid to starch digestion. It is made by the vacuum process which protects its enzymatic activity from injury by heat. As a vehicle for the vitamins contained malt extract is ideal. The flavour of the finished product is very pleasing and is, therefore, logically indicated for children who are under-weight, have little appetite or who have not regained normal vitality after some acute infection. Also for adults for the same conditions and during pregnancy and lactation or other periods of stress. A tablespoonful added to the 24 hours supply of the baby's formula will ensure an abundant supply of vitamins A, B and D, will protect against secondary anæmia, and has nutritive value equivalent to approximately 3 ounces of whole milk.

Ferradol supplies 4 calories per gramme or 48 calories per fluid ounce.

Messrs. Parke, Davis and Co. offer this product in 1 lb. cylindrical glass jars.

EMOCAL

An organic calcium preparation for use in pulmonary tuberculosis

For some time the organic compounds of calcium have been utilized for the treatment of tuberculosis. De Renzi has reported that there is a direct connection between the quantity of phosphate of calcium contained in the urine and the loss of flesh of the patients suffering with tuberculosis; and that is, he noticed, that the patient's weight increased or diminished in accordance with the increase or decrease of the salts of calcium eliminated.

To-day it seems that decalcification and the increase of the organic combustion constitute the dominating factors with the battle against tuberculosis. Thus we find that, while the lack of calcium can be considered as the specific and predominating stigma of pre-disposition towards tuberculosis, the calcification of the tuberculous lesions appears to be one of the essential conditions of local cure.

Naturally in regard to therapeutics the organic preparations of calcium should be preferred both because they are more easily assimilated, and because no intolerance whatsoever is met with. Amongst these last-named preparations, I have no hesitation whatsoever in declaring that Zambelletti's EMOCAL is the best because it corresponds in every way to the therapeutical requirements and, besides this, the preparation in question is not eliminated by the emunctory ducts and therefore remains longer in the body thus offering to the latter the maximum therapeutic utilization of the calcium. This preparation is put up in ampoules for intramuscular injection and for intravenous injection. I have always given preference to the latter method since the intravenous injections are exempt from any

inconvenience whatsoever and give the best results more rapidly than the former.

It will, of course, be easily understood that the intravenous injections cannot be continued for a very long time and therefore it is both necessary and useful, after a series of from 15 to 20 intravenous injections, to give the patients another series of intramuscular injections of the same preparation which however do not give rise to any local reactions.

DR. GIACOMO GARGIULO.

The agents for Emocal in India are Stella and Co., Box 868, Bombay.

ELECTRO-MEDICAL APPLIANCES

MALGHAM BROTHERS have written to inform us that Mr. Hirji Malgham is proceeding on a second tour to Europe and will devote considerable time in the well-known factories of The British Hanovia Quartz Lamp Co., Ltd., and Messrs. Schall and Son, Ltd., both in London, makers of the famous Quartz U.V.R. lamps and of pantostats, diathermy units and electro-surgical tissue-cutting apparatus, etc., respectively.

The main idea of this second tour to Europe is to add greater knowledge in the technique of handling electro-medical appliances and to give better and more efficient service than hitherto to the medical profession.

Any member of the medical profession or any hospital requiring first-hand information whilst Mr. Malgham is in Europe will be welcome to write without the least obligation Messrs. Malgham Bros., 20, Western House Road, Bombay.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE ANÆMIA OF KALA-AZAR

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.
and

L. R. SHARMA, M.B., B.S., M.R.C.P.E., D.P.H. (Camb.),
D.T.M. & H. (Camb.)

(From the Kala-azar Enquiry, Indian Research Fund
Association, School of Tropical Medicine, Calcutta)

It has always been recognized that a considerable degree of anæmia is the rule in a person suffering from kala-azar. It has also been recognized that when the patient is cured this anæmia disappears, *pari passu* with his return to normal health. But because from a diagnostic point of view there is little significance in this anæmia, a similar degree of erythropenia being present in the majority of the conditions which are likely to be confused with kala-azar, because more valuable diagnostic information may be obtained from the leucocyte counts, and because if the specific disease is cured the anæmia requires no special treatment, clinicians, who pay the most careful attention to the leucopenia, both for making a diagnosis and for gauging progress, have been led to ignore altogether the erythropenia. Even the leading authorities give little attention to this particular aspect of the disease. Rogers (1910) gives a table (unfortunately based on patients in a European hospital) showing that the erythropenia is progressive—not marked in the early stages but becoming 2,500,000 per c.mm. and even less in more advanced cases. Brahmachari (1928) quotes this and adds his own experience that in 7.5 per cent of cases the count is above 4,000,000, in 60.5 per cent between 4,000,000 and 2,500,000, in 24.5 per cent between 2,500,000 and 1,500,000 and in 7.5 per cent below 1,500,000. Knowles (1920) gives the mean for 33 cases as 2,457,270, from 1,416,000 to 3,728,000. Napier (1930) gives the typical blood count in a case of six months' duration as about 3,000,000 and Manson-Bahr (1929) says that the count is often over 4,000,000 and usually over 2,500,000 even in advanced cases.

Little attempt has been made to classify the anæmia, and none to explain its cause. Brahmachari refers to presence of 'poikilocytes, micro- and melagocytes, myelocytes, and erythroblasts' in the peripheral blood. Rogers gives the colour index as 0.65 which he says is about normal for the Assamese on whom this figure was based, and he considers the anæmia to be of the 'pernicious' type, whereas Brahmachari considers that it is more often of the 'chlorotic' type; this suggestion is supported by his finding of a low colour index, but not by his statement regarding the presence of

abnormal cells usually associated with pernicious anæmia.

It is rather surprising that this well-marked and constant departure from the normal has claimed so little of the attention of the investigators in this disease. With the opportunities at our disposal we felt that we should investigate certain points in this aspect of the hæmatology of kala-azar.

It is of course extremely difficult to give a concise account of the blood picture in kala-azar on account of the frequency with which the disease is associated with other infections which must necessarily complicate the picture by introducing contradictory elements. Nearly all our patients in Calcutta have had malaria and are suffering from its after-effects to varying extents; a very high percentage have an ankylostome infection, but few have a heavy enough one to merit the description 'hook-worm disease'; and various concomitant helminthic, bacterial and protozoal infections are frequently encountered. To obtain the most certain and dramatic results with the pentavalent antimony compounds it is advisable to treat these co-existent infections first but in order not to depart too far from 'field' conditions where such a procedure would be impossible we have not usually adopted this plan but have made a practice of treating the kala-azar first and the residual infections, if necessary, afterwards. There is in the majority of cases such a rapid and complete return to normal, despite latent malaria and a mild ankylostome infection, that one is driven to the conclusion that the anæmia is mainly due to the leishmania infection. However, for this enquiry we have chosen patients with no obvious additional infections so as to eliminate, as far as possible, this complicating factor.

The cases were all Indians; the majority had been living in Bengal for years. They were patients in the hospital attached to the Calcutta School of Tropical Medicine. In every case the diagnosis of kala-azar was confirmed by the finding of the parasite.

The total red blood cell count

All authorities agree as to the constant presence of erythropenia, and amongst those who are writing from practical tropical experience there is little difference in their opinion as to the degree of the deficiency. Knowles gives the lowest figures, but his cases had been selected, usually for their severity, and are not a fair sample of the general kala-azar population. We considered the question of collecting and analysing the red blood cell counts from the case notes of patients treated during the last twelve years in the Carmichael Hospital for Tropical Diseases, but we felt that, as these counts had been made by a number of different observers with a number of different (often indifferent) instruments, the results would not

repay the labour entailed and we decided to depend on the counts made during this investigation—which, though comparatively small in number, were made under standard conditions with a good hæmocytemeter—for confirming the observations of other workers.

The counts were made from peripheral blood obtained by pricking the finger. The counts were made about the same time each day and not immediately after a meal. The red blood cell count was done by the usual method with a one-in-a-hundred diluting pipette and a Thoma-Ziess counting chamber. At least 192 squares were counted each time.

As a preliminary measure counts on 10 'normal' Indians, workers in the laboratory, were done; these ranged from 4,775,000 per c.mm. to 6,106,000 and the mean was 5,429,600.

As a further normal control, counts were done on nine patients suffering from dermal leishmaniasis, a condition not usually associated with any general disturbance. The mean of these nine counts was 5,108,000, the lowest being 3,650,000 and the highest 5,957,000; the two patients with the lowest counts were evidently debilitated as they improved considerably during their course of treatment for the skin condition; if these two counts are excluded the remainder fall into line with the other controls.

Of 81 counts done on 47 kala-azar patients before they received specific treatment of any kind the mean was 2,930,395; the highest count was 4,766,000 and the lowest 1,890,000.

It will however be best to take the first count in each case. The mean of these 47 counts is $2,880,000 \pm 54,568$ (probable error). One was below two millions and six were over 3,500,000: that is to say 85 per cent were between these two figures.

Influence of various factors on the blood count

Sex.—The mean of the counts in the eleven female cases was 2,741,000, and in the 36 males 2,922,000.

Age.—The mean of the counts in the seven children under 10 years of age was 2,578,000, in the 13 patients aged between 10 and 20 years it was 2,902,000, and in the 27 adults it was 2,947,000.

Duration of the disease.—The mean of the counts of 13 patients who gave a history of less than six months' duration of illness was 3,042,000; of 18 patients with a history of more than six months but less than a year the mean was 2,871,000; and of the remaining 16 who gave a history of a year or more the mean was 2,757,000.

Size of the spleen.—This was less than three inches below the costal margin in 13 cases, the mean of the count in these being 3,003,000; the spleen was three or more but less than six inches in 17, the mean of the count in these being 2,914,000; and in the remaining 16 in which

the spleen was six inches or more the mean of the count was 2,744,000.

Duration of the stay in hospital.—Nearly all the patients were markedly improved by rest in bed and hospital diet alone. Fourteen patients had been in hospital three weeks before the first count was made; the mean of the counts in these cases was 3,344,000, as against a mean of 2,682,000 for the 33 who had been in a shorter time than this.

Conclusions.—The count in young children seems to be lower than in adults, and in females the count is slightly lower than in males. The duration of the disease, as evidenced by the history and the size of the spleen, does not appear to be a very important factor, and the evidence for the steadily progressive nature of the anæmia which Rogers (1910) claimed, is lacking; on the other hand the observations suggest that a moderate degree of anæmia is rapidly acquired and that subsequently this increases very slowly. It is however apparent that the length of the stay in hospital is an important factor. None of these patients had had more than symptomatic treatment, e.g., purgatives and cough mixtures, but they were all on a full diet. This diet was in most cases better than the patients received in their own homes; in the case of the poorer class patients because they could not afford a better diet, and in other cases because it is a common practice in Bengal to 'starve a fever'. The chart given below is an extreme example; this woman came

FIG. 1

Note improvement in count prior to any treatment

from a well-to-do household but had been kept on a very low diet for some time.

The reactions of the red blood count under various forms of treatment will be discussed below.

The reticulocyte count

A reticulocyte count was made on each occasion with the red cell count. The technique adopted was as follows:—

Technique.—The slides were carefully cleaned by immersion in sulphuric acid and potassium bichromate solution, subsequently washed in running water and finally in distilled water. One side was marked, and then polished with jewellers' rouge. The slide was then

dipped in a 0.75 per cent solution of brilliant cresyl blue in absolute alcohol, and transferred rapidly to a cylindrical specimen bottle at the bottom of which had been placed a piece of filter paper, and the cork replaced in the bottle. The slide is allowed to stand upright in this bottle until it is dry. This ensures slow drying and an even distribution of the film of dye. A suitable sized drop of blood obtained from a finger prick is taken on to a specially cleaned cover-slip, $\frac{3}{4}$ by $1\frac{1}{2}$ inches, which is immediately dropped on to the stain-covered slide. The drop of blood is of such a size that when very gentle pressure is applied to the cover-slip the blood just fails to reach the edge. The edges are now sealed with paraffin wax which is melted and applied with the aid of a match.

An Ehrlich's eye-piece or some similar device is used to restrict the microscopic field. A succession of fields is then counted, the total number of red cells, the number showing reticulation noted and the percentage calculated; the actual numbers are then calculated from the total red cell count which was done at the same time.

At the beginning of the investigation we adopted the practice of counting as reticulocytes only those cells in which there was definite reticulation, not counting those in which there were only a few isolated dots taking the stain. This accounts for the fact that our 'normal' counts are lower than those found by the majority of observers. Later, we noted down both the number of young reticulocytes (the definitely reticulated cells) and the older reticulocytes (those showing isolated dots only); we found that in the kala-azar cases the young reticulocytes constituted about 60 per cent of the total reticulocytes, but that often after treatment it was possible only to find older reticulocytes. The figures we give in this paper refer to young reticulocytes only, unless it is stated otherwise, so that for comparing our counts with those of other workers about 40 per cent should be added to our figures.

Normal controls.—Counts were done on 10 healthy Indian males, laboratory workers. 1,500 to 2,000 red cells were counted in these as the counts were low. The counts varied from 0.1 per cent to 0.63 per cent, the mean being 0.42. The mean actual number of reticulocytes was 22,790 per c.mm.

Of the nine cases of dermal leishmaniasis the mean reticulocyte percentage was 0.67 and the mean reticulocyte count 34,224 per c.mm.

Kala-azar cases prior to any treatment.—The mean reticulocyte percentage in 82 counts in 47 cases was 2.07 per cent; only one was over 4 per cent, 13 were over 3 per cent, 36 between 2 and 3 per cent, 27 between 1 and 2 per cent, and six under 1 per cent. Two counts only were below the mean normal, i.e., 0.42, and these were both in the same case.

The mean of the reticulocyte counts was $60,743 \pm 1,593$ (probable error) per c.mm. There were 10 counts over 80,000, the highest being 137,000, and only four under 30,000, so that 82.9 per cent of the counts were between these two figures. The same two low counts (from one case) were the only ones below the mean normal count.

Abnormal red cells.—No nucleated red cells were observed in the whole series. There was no marked poikilocytosis or polychromasis, and, although there were differences in the sizes of

the red cells, no frank microcytes and few macrocytes were seen.

The effect of antimony treatment

Controls.—We could not very well keep a normal man in hospital for some weeks and subject him to a course of neostibosan injections, so we took three cases with only dermal lesions as controls. One of these was a hospital patient whose red blood count had risen from three and a half to five millions before treatment was given; 17 days after the completion of a course of 12 daily injections it rose to 5,400,000 and the reticulocyte count which had been 30,000 fell to 12,000. In another the counts, which were originally within the normal limits, fell slightly, but still remained within the normal limits. In a third case there was a distinct rise in the red cell count, from 4,125,000 to 5,125,000, during a course of about two months in which injections were given twice a week. She was an out-door patient throughout, and had no other treatment, but her general condition improved; it is of course possible that the effect was a psychological one, consequent on the disappearance of the disfiguring skin lesions; the reticulocytes fell from 36,000 to 10,000 during the same period.

It is evident that the antimony injections do not have any marked and immediate effect on the red cell or reticulocyte counts. A typical chart is given.

FIG. 2

A case of dermal leishmaniasis

Kala-azar cases.—There were 12 cases in which antimony treatment only was given; in two of these the red blood cell count was just over four millions, in six it was between three and four millions, and in the other four it was between two and a half and three millions. The reticulocyte count varied between 0.72 and 3.14 per cent. In most instances two counts before and two counts during treatment were

done; the means of the counts are given below :—

TABLE I

Antimony treatment only; means in 12 cases

Relationship to treatment	Red cells per c.mm.	Reticulocyte per cent	Reticulocytes, actual number per c.mm.
Before ..	3,258,000	1.59	51,802
During ..	3,364,000	1.09	36,668
After 1st week	4,208,000	0.49	20,619
2nd week	4,313,000	0.32	13,802
3rd week	4,589,000	0.30	13,767

Two characteristic graphs are also given.

FIG. 3

FIG. 4

It will be seen that from the commencement of treatment there was a fall in the reticulocytes, but the increase in the total red cells did not occur until the first week after the treatment was finished. The reticulocytes continued to fall and by the time the patient was discharged they had in every case fallen to less than 0.6 per cent, and in some no reticulocytes could be seen in a dozen fields.

Three other patients were given experimental vaccine treatment. There is no reason to suppose that in any instance did this treatment have any beneficial effect on the course of the disease; in two there was no appreciable effect on the red cells or the reticulocyte count until the course of neostibosan was given. The graph of the third case is given below; it will

FIG. 5

be seen that there was a slight improvement in the red blood count during the vaccine course, but that this count had already been rising before and that the antimony treatment, when it was eventually given, had the usual and immediate effect of improving the red blood count and reducing the reticulocytes.

In the cases already referred to, the patients responded well clinically to treatment, but in one case there was no such clinical response. In this case there was no improvement in the red cell count, and though the reticulocyte count fell slightly, it still remained above normal.

The effect of the administration of other therapeutic agents

With the object of obtaining some clues as to the mechanism of anaemia in kala-azar, we administered to our patients a number of different therapeutic agents that are of value in the treatment of various forms of anaemia.

Iron.—In five cases large doses of iron were given. This was usually ferri et ammonii citras in doses of twenty grains three times a day. The red blood cell count prior to treatment in all these cases was between two and a half and three millions. During the iron

FIG. 6

administration both the reticulocyte count and the red blood count tended to fall, but with the administration of neostibosan the reticulocyte count fell sharply and the total red cell count immediately started to improve; the final rise in the number of reticulocytes was due to a sharp rise in one case. The means of the five cases are given below in tabular form:

TABLE II
Iron treatment

Relationship to treatment	Red cells per c.mm.	Reticulocyte per cent	Reticulocytes, actual number per c.mm.
Before ..	2,698,000	2.70	72,846
During iron treatment—			
1st week	2,557,000	2.04	52,163
2nd week	2,356,000	1.70	40,032
3rd week	2,403,000	1.53	36,766
During antimony	2,972,000	1.27	37,744
After antimony—			
1st week	3,405,000	0.88	29,961
2nd week	3,603,000	0.46	16,574
3rd week	4,681,000	0.76	35,576

The graph of a typical case is also given.

Liver therapy.—Intravenous hepatex was given in four cases. The doses, 1.5, 3.5, 5 c.cms., etc., were given on successive days. Three, three, four and seven doses were given, respectively. During and after the administration of hepatex frequent (at 48 hours intervals) blood counts were done in order not to miss any reticulocyte crisis that might occur. One of the patients who had three doses of hepatex was very debilitated; her red blood count, 3,125,000, tended to fall slightly, but her reticulocyte count which was just over 60,000 fell to below 6,000 on the fifth day from the commencement of the treatment and never rose again. On the tenth day the patient, who had been in a collapsed condition for twenty-four hours, died; she did not suffer from any complicating infection to account for her sudden death and no post-mortem examination was allowed. In the other cases there was a slight downward tendency of both the red cell and the reticulocyte counts during and after the hepatex administration, but the usual reaction followed the administration of antimony. A graph of a typical case and a table showing the means of these four counts are given below; the figures for 'during' and 'after' treatment refer to only three cases.

FIG. 7

TABLE III
Liver treatment

Relationship to treatment	Red cells per c.mm.	Reticulocyte per cent	Reticulocytes, actual number per c.mm.
Before ..	2,887,000	2.48	71,598
During hepatex	2,721,000	2.10	57,141
After hepatex	2,534,000	1.81	45,865
During antimony	2,662,000	2.37	63,089
After antimony—			
1st week	2,813,000	1.65	46,414
2nd week	3,728,000	1.31	48,837
3rd week	4,275,000	0.89	38,047

Another patient was given liver extract by the mouth. His red cell count was 2,000,000 and his reticulocyte count 64,000 (3.2 per cent) before he took the liver extract; the former underwent little change during the liver treatment but later, when the course of neostibosan was given, it fell sharply to below a million and then rose again very slowly to 2,500,000. The reticulocyte count rose to 99,000 during the liver treatment, fell again to 27,000 and then again rose sharply to 105,000. At this stage the patient was obviously not cured from a clinical point of view and a further course of injections were prescribed, but we were not able to follow the course of the blood picture further in this case. This was the only case in which there was a rise in the reticulocytes that in any way resembled a reticulocyte 'crisis', but, even making allowances for our different standard for judging reticulocytes, it could not be compared with the reticulocyte rise that occurs in cases of pernicious anemia following liver administration.

Marmite.—Six patients were given marmite for two to three weeks soon after admission. In one case there was a slight fall in both the red cell and in the reticulocyte counts; in four there was a slight rise but this did not amount to more than is usual in all cases after admission; but in one there was a very distinct rise in the red cell count, from two and a half millions to four millions. In no case was there a reticulocyte 'crisis'; in one case there was a rise from 75,000 to 120,000, but in the others there was a slight rise or a slight fall. On the administration of antimony the patients reacted in the usual way. A table showing the means of the six counts is given, and also a typical chart.

FIG. 8

TABLE IV
Marmite

Relationship to treatment	Red cells per c.mm.	Reticulocyte per cent	Reticulocytes, actual number per c.mm.
Before any treatment.	2,703,000	2.16	58,384
During marmite—			
1st week	3,045,000	2.26	68,817
2nd week	3,287,000	1.95	64,095
During antimony	3,495,000	1.75	61,162
After treatment—			
1st week	3,994,000	1.05	41,937

Final ..	4,436,000	0.20	8,872

Bcmax.—One patient was put on this food on account of the reputed high vitamin-B content. There was a slight increase in his red cell count and a slight fall in the reticulocytes.

Cinchona alkaloids.—In two cases in which scanty malarial parasites were found in the peripheral blood, quinine and cinchona febrifuge, respectively, grains 10, twice daily, was given. In one case the fever was controlled temporarily, in the other it was not affected. In neither case did the alkaloid have any effect on the red cell or reticulocyte counts; in both, the administration of neostibosan led to a rapid return towards normal. A chart of one case is given below.

FIG. 9

Adrenalin.—Adrenalin has been said to have a stimulating effect on the bone marrow, and, in view of the fact that there is evidence of hypoadrenia in kala-azar, we gave four patients a course of injections of adrenalin, 0.5 c.cm. of a 0.1 per cent solution daily for a week to 10 days.

There is no evidence that these injections had any effect on the red cell or reticulocyte counts. A table is given below showing the means of the counts before any treatment, after the adrenalin course was completed, and during and after the antimony course. The apparent rise in the count after the adrenalin is due to general improvement in the patients after admission; in only one out of four cases was there a rise between the last count before adrenalin and the first count after adrenalin. There was, if anything, a slight fall in the reticulocyte count following adrenalin. The counts behaved in the usual way after neostibosan was given. A characteristic chart is shown.

Hæmoglobin

Napier (*loc. cit.*) gives the hæmoglobin percentage ('based on European standards') as 60 and the colour index as 1 in a typical case of kala-azar of six months' duration.

Rogers' statement that the colour index is 0.65 and that this figure is about normal for the Assamese is difficult to understand and to correlate with his further statement that the anæmia is usually of the pernicious type. Brahmaehari (*loc. cit.*) writes 'The average colour index in this series of cases is 0.64, and in nearly 10 per cent of them it was nearly equal to the average normal in Indians'. The difficulty in understanding the meaning of these statements can to a certain extent be accounted for by the confusion that exists regarding the meaning of the expressions 'hæmoglobin percentage' and 'colour index'. The only satisfactory definition of the former is 'the number of grammes of hæmoglobin in 100 cubic centimetres of blood', though by it most writers mean the percentage hæmoglobin compared with an arbitrary normal the hæmoglobin value of which they fail to state. The colour index is necessarily a relative figure and is best arrived at by working out the normals for males from the class from which the patients are drawn and making unity the normal index.

The usual clinical methods of estimating hæmoglobin are notoriously unsatisfactory, and, as at the beginning of the investigation no very

5. Normal red cell.

satisfactory method had been adopted by us for rapid estimation of the hæmoglobin, this was not made as a routine measure. However, a rough estimation was usually made by means of the ordinary Tallqvist scale. In 15 cases this estimation was checked by the readings with a Fleischl-McIsheer hæmoglobinometer and the necessary corrections made in the rest of the readings. Thus, a high degree accuracy cannot be claimed for all these observations but they are probably as accurate as any so far published; the results are therefore recorded.

Of 63 observations in 32 cases before any treatment whatsoever was given, the maximum was 11.25 grammes of hæmoglobin per 100 c.cm. of blood and the minimum 4.2 grammes. The mean was 7.08 grammes and the probable error 0.084.

Of 28 observations made on 28 patients just before they were discharged as cured the maximum was 15 grammes, the minimum 8.25 grammes and the mean 12.01 grammes per c.cm. of blood.

Colour index.—Taking the normal hæmoglobin of the patient class as 15 grammes and the normal red blood cell count as 5,400,000, we estimated the colour index before treatment as from 0.65 to 1.08, with a mean of 0.885, and at the time of discharge as from 0.847 to 1.21 with a mean at 1.005.

The size of the red cells

For estimating the mean size of the corpuscles Eve's halometer was used. The estimation was made in 22 cases before any treatment was given and at the time the patient was discharged cured. Before treatment the mean was 7.559μ and at the time of discharge 7.375μ . Using the same instrument the same observer made 50 estimations in 10 normal Indians, obtaining a mean of 7.216μ .

Fragility of the red blood cells

This was tested with different strengths of sodium chloride by one of the usual methods. A number of normal bloods were first tested; the means of the concentration at which hæmolysis commenced was 0.427 per cent and at which it was complete was 0.36 per cent.

The estimation was made in 35 cases before treatment and in 23 of these, before, during and after treatment. The room temperature was usually between 33°C . and 28°C . In nearly every instance the cells were found to be more resistant than normal to hæmolysis; in one case only did hæmolysis commence and in only two was it complete at a higher salt concentration than is the case in normal bloods. After treatment the fragility returned to normal. The means of the readings are given below in tabular form.

TABLE VI

	Hæmolysis commenced	Hæmolysis complete
Before treatment	0.3913	0.3321
During "	0.4100	0.3573
After "	0.4236	0.3636
Normal control	0.4266	0.3616

The fragility of the reticulocytes

The reticulocyte percentage was estimated in a tube in which no hæmolysis occurred and in the last tube in which submaximal hæmolysis occurred. It was found in the cured cases and controls that the percentages were about equal or, if anything, the percentage was lower in the tube in which some hæmolysis had occurred, but in cases prior to treatment there was a marked increase in the tube where partial hæmolysis had occurred, indicating that the reticulocyte in kala-azar is more resistant than the older red cell.

The Arneth count

The count was done in 30 kala-azar cases before treatment: the mean of the Arneth indices was 92.67. In 10 cases only was it done again after treatment. The means of these 10 counts before and after treatment, and the means of the Arneth indices are given below:—

Groups	I	II	III	IV	V	Index
Before treatment	49	36	12	3	0	91.8
After "	34	38	19	8	1	81.3

It is apparent that there is a very marked shift to the left and that the count had not returned to normal at the time the second count was done. The personal factor must play an important part in the working of this count; in this case control counts on normal persons showed that the writers had a tendency to make counts with a higher Arneth index than normal, but there can be no doubt there is a very marked shift to the left in kala-azar cases, as the fact was confirmed for us by an independent worker.

Other investigations

Urobilinuria.—The urine was examined qualitatively for urobilin in 39 cases before treatment and, in the majority of these, during and after treatment. The results were given as 'no definite increase', 'definite increase', 'marked increase' and 'very marked increase'. In nine cases no definite increase was noted on the first examination, but in two of these there was an increase at the time of some subsequent examination prior to treatment; that is to say a definite increase was demonstrated in 32 (or

82 per cent) cases before treatment. The table shows the findings summarized:—

TABLE VII
Urobilinuria

	First examination before treatment	During treatment	After treatment	Examination one month to six weeks later
Very marked increase.	18	13	13	1
Marked increase	3	10	5	1
Definite increase	9	7	5	2
No increase of urobilin.	9	5	9	3

Four cases in which no urobilin was found before showed a definite increase after or during treatment, and in three cases, in which there was definite increase before, there was none after treatment. In the fourth column of the table only those cases in which there had been a very marked increase throughout are included; it will be seen that in some the urobilin persisted for a long time.

Lævulose-tolerance test

This was done in six cases before treatment and in four of these after treatment. The results were within the normal limits, except in one case prior to treatment; in this case after the administration of 25 grammes of lævulose there was a rise from 75 to 96 milligrammes per 100 c.cm. in the blood-sugar, and the level was maintained at about 90 for two hours.

The van den Bergh test

This was done in five cases; in four of these it was done both before and after treatment. The 'direct' reaction was negative throughout. The 'indirect' reaction was positive in four and doubtful in the fifth before treatment, but negative after treatment. These cases were included in the six in which the lævulose-tolerance test was done; in all of them there was urobilinuria, both before and after treatment.

Summary of the observations

Red cell count.—The mean of the first counts in 47 cases of kala-azar was 2,880,000 per cubic millimetre and the probable error of this mean $\pm 54,568$. In only one case was the count below two millions, and in six it was above three and a half millions. In 34 subsequent counts on some of these patients prior to treatment the mean was 3,000,000. The counts were lower in women, and in children they were lower than in adults.

Duration of the disease did not appear to influence the count very much, but the length of time the patients had been in hospital seemed

to be an important factor. The blood count improved without treatment in nearly every case; better food was probably the cause of this improvement. Abnormal red cells were not noted in any of the 47 cases.

Reticulocyte count.—With the technique and criteria we adopted the normal was 0.42 per cent, or 23,000 reticulated cells per c.mm.

Before treatment in 82 counts in 47 patients the mean percentage was 2.07; the mean of the count was 60,743 per c.mm. and the probable error of this mean $\pm 1,593$.

The effect of antimony treatment.—The administration of neostibosan was always followed by a sharp fall in the reticulocytes and an increase in the red cell count; at the end of the third week after treatment the mean red cell count had risen to 4,589,000 and the mean reticulocyte count had fallen to 13,767 per c.mm.

Administration of other therapeutic agents.—The effect of the administration of iron, liver, marmite, adrenalin, and the cinchona alkaloids was tried. In the case of marmite there was a slight, but doubtful-significant, improvement in the red cell count; in no other case was there any significant improvement in the blood picture. In no instance was there a reticulocyte crisis, and in most cases the reticulocyte count fell slightly. In every instance the red cell and reticulocyte counts reacted in the characteristic way on the subsequent administration of antimony.

Hæmoglobin.—Before treatment the mean of 63 observations on 31 patients was 7.08 grammes per 100 c.cm. of blood and the probable error of the mean ± 0.084 gramme, the maximum was 11.25 grammes, and the minimum 4.20 grammes.

After treatment and just prior to discharge, the mean of 28 observations on 28 patients was 12.01 grammes per 100 c.cm. of blood, the maximum was 15.00 and the minimum 8.25.

Colour index.—Taking the normals as 15 grammes and 5,400,000, respectively, the mean index was 0.885 before treatment and 1.005 at the time of discharge.

Halometric readings.—Mean size before treatment was 7.559 μ , and after 7.216 μ .

The fragility of the red cells.—The resistance of the red cells to the action of hypotonic saline was increased prior to treatment, but it returned to normal after treatment.

The Arneth count.—There was a very marked shift to the left in all cases before treatment; this shift was still apparent after treatment, but had been modified; the means of the Arneth indices before and after treatment were 91.8 and 81.3, respectively.

Urobilinuria.—There was a distinct increase in the urobilin present in 32 out of 39 cases before treatment, and in 36 out of 39 at some time during the course of the disease. In the majority of cases there were large quantities present throughout the course of the disease,

and for some weeks after treatment was completed.

Liver function tests.—In only one out of six cases was there any evidence of levulose intolerance prior to treatment; in this case the blood-sugar rose by 21 milligrammes, and remained above normal for 24 hours. After treatment no intolerance was demonstrable. In four out of five cases the van den Bergh 'indirect' reaction was positive before treatment, and in the fifth the reaction was doubtful. The 'direct' reaction was negative throughout, and the 'indirect' reaction was negative in all cases after treatment.

Discussion

This does not claim to be a complete investigation of the anæmia of kala-azar; there are many lacunæ which other workers will perhaps fill. Nevertheless, we have thought it worth while to summarize our findings and examine them to see if we can draw any conclusions as to the nature of this anæmia, more especially as the opportunity for continuing the investigation does not at present exist.

It is clear that in kala-azar there is a remarkably constant anæmia; it is more or less normocytic (the halometer readings being only slightly above normal) and it is hypochromic. It does not react to the common hæmatinic agents that we gave, nor does significant improvement follow the treatment of complicating factors such as malaria (it should perhaps be explained that in no instance during the investigation did we encounter a patient suffering from a hook-worm infection sufficiently large to suggest that this helminthic infection was causing any significant anæmia), but it reacts almost immediately to pentavalent antimony, the specific for this disease.

It is justifiable to assume that the production of anæmia is a part of the morbid process in kala-azar, but it is a matter for discussion as to how the anæmia is brought about. For purposes of discussion let us take this simple classification of anæmias:—

(a) the true secondary anæmias due to loss of whole blood from the skin, mucous or serous surfaces; this loss may be acute or chronic,

(b) anæmias due to errors in erythrocytogenesis; these may be due to

(i) aplasia or hypoplasia of toxic, nutritional, or obstructive mechanical origin,

(ii) dysplasia; these are mainly deficiency anæmias which may be macrocytic or microcytic according to the stage at which hæmopoiesis is interfered with,

(c) anæmias due to errors in erythrolysis; these again can be divided into anæmias

(i) due to defects in the red cells themselves caused by parasitization or the effect of poison, or of congenital origin,

(ii) hyper-function of the reticulo-endothelial tissues responsible for the disposal of obsolete red cells.

It is obvious that the anæmia cannot be a true secondary anæmia, (a) in our classification, because although small hæmorrhages from mucous membranes are common, they are not a constant occurrence.

Melleney has pointed out that kala-azar is essentially an infection of the reticulo-endothelial system, and he and other workers have shown that in the bone marrow in this infection there is a marked increase in the histiocyte tissue, replacing the fat and eventually the normal hæmatopoietic tissue. This invasion of the bone marrow commences early in the infection, but at first it does not appear to interfere much with the blood-forming elements; the invasion is, however, progressive and in the rib marrow in human cases it appears eventually to displace the hæmatopoietic tissue completely. Such a state of affairs must eventually bring about anæmia of the hypoplastic kind, and hitherto this has been accepted as the explanation for the leucopenia and anæmia characteristic of kala-azar; there are, however, certain points to be considered. Firstly, the leucopenia and the erythropenia appear early in the infection and are not essentially progressive, whereas at this stage the amount of replacement of hæmatopoietic tissue is not serious and the reserves of the hæmatopoietic system are known to be very large; secondly, the moderate reticulocytosis and the marked shift in the Arneeth count to the left do not suggest a hypoplastic origin; and, thirdly, there are certain other observations, such as the evidence of increased hæmolysis, which require explanation.

It has been suggested that the anæmia might be an aplastic anæmia of toxic origin, but the evidence of the presence of any toxin in leishmania infections is very slender. There is evidence that the anæmia is increased by a low dietary, but improvement is slight and can only be brought up to a certain point by increasing the diet.

Again the evidence that it is not a dysplasia due to some deficiency (*e.g.*, Castle's intrinsic factor, vitamins, or iron) cannot be said to be complete as the possibilities are inexhaustible but we failed to get any significant improvement—evidenced either by an increased red cell count or by a reticulocytosis—with our trials in supplying the most likely deficiencies, and furthermore the anæmia disappeared on the administration of antimony alone which cannot be classed as an essential factor for hæmatopoiesis.

On the other hand there is considerable evidence of increased red cell destruction. There was in almost every case a moderate but definite reticulocytosis, much the same degree of reticulocytosis that occurs in a moderately heavy malarial infection, where it is definitely

known that red blood cells are destroyed. There was again a constant very marked urobilinuria and an 'indirect' van den Bergh reaction, evidence of increased hæmolysis and/or inability of the liver parenchyma cells to metabolize the products of hæmolysis. There is no histological evidence that the parenchyma cells of the liver are damaged in the uncomplicated case of kala-azar, and the lack of evidence of lævulose intolerance and the fact that the 'indirect' van den Bergh reaction rapidly becomes negative after treatment, all tend to indicate that the urobilinuria is due to excessive hæmolysis rather than hepatic deficiency.

The excessive hæmolysis provides a stimulus for increased erythropoiesis which is evidenced by the reticulocytosis. On the administration of antimony this increased destruction ceases and with it the stimulus for increased production also, so that the organism, being attuned to a blood supply with a lower oxygen-carrying capacity than normal, ceases to demand an excessive hæmatopoiesis, which then continues more or less normally until the normal number of red blood cells have been provided.

The evidence of the existence of a toxin, which might be held responsible for this hæmolysis, is lacking, and there is no parasitization of the red cells, as is the case in malaria, nor is there any other defect in the red cells to account for the increased hæmolysis. Our fragility tests indicate on the contrary that the red cells are tougher than normal, which suggests that the combing out of obsolete or defective blood cells is more thorough in this disease than it is in normal man, that is to say, there is a hyperactivity of the normal mechanism of erythrolysis. This is conceivable in view of the fact that marked proliferation of the cells of the reticulo-endothelial system—the system concerned in erythrolysis—is the characteristic feature of generalized leishmania infection.

We cannot here go into the question of the mode of action of antimony in this disease, but our observations (Napier, Krishnan and Lal, 1933) suggest that antimony acts through the reticulo-endothelial system, possibly in this case by paralysing the newly-formed reticulo-endothelial cells so that they can no longer phagocytose red cells; this would lead to the death of the contained parasites and the cells themselves would eventually become lysed. If this occurred one would expect the immediate cessation of excessive hæmolysis and the slower disappearance of urobilinuria, which would naturally continue until the parasitized reticulo-endothelial cells had all been lysed and the products of this excess metabolism had been excreted; there is evidence that this does occur.

By way of conclusion we can say that there is some evidence that the anæmia of kala-azar is caused by increased erythrolysis, and it is suggested that this may be a direct result of

(Continued at foot of next column)

THE TOXICITY OF TETRACHLORETHYLENE TO CATS

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
and

R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

(From the Pharmacological and Hookworm Research Departments, School of Tropical Medicine, Calcutta)

FOLLOWING the successful use of tetrachlorethylene in other parts of the world in the treatment of hookworm infection, Maplesstone and Mukerji (1929) tried this drug in Calcutta, but they came to the conclusion that it was not so efficient as carbon tetrachloride and that it also appeared to be just as toxic as the latter drug, and therefore its use was discontinued at the Calcutta School of Tropical Medicine. Recently, however, we have been led to modify somewhat this opinion, so it was decided to give tetrachlorethylene another trial. The work of Lamson, Robbins and Ward (1929) clearly showed that tetrachlorethylene is not so toxic to animals as is carbon tetrachloride, but on account of the surprisingly fatal effects of the latter on cats in Calcutta, a fact which was demonstrated by Chandler and Chopra (1925), and which was not in agreement with the findings of American pharmacologists, it was considered advisable to test tetrachlorethylene also on Calcutta cats before using it again in the treatment of human beings. This work has now been done, and as the same methods of administering the drug were employed in this investigation as were employed with carbon tetrachloride by Chandler and Chopra, the results of their experiments and those of the present

(Continued from previous column)

the general increase in the tissue and blood histiocytes—the characteristic reaction to the leishmania infection.

Acknowledgments

Our thanks are due to Dr. A. K. Mukerji for taking the halometric readings, and to Dr. J. P. Bose for doing the van den Bergh and lævulose-tolerance tests.

series of tests with tetrachlorethylene form a useful basis for comparison of the effects of the two drugs.

Tetrachlorethylene both in milk and in water was given to cats but no difference in the type or severity of symptoms was observed in the two series. The commencing dose of tetrachlorethylene employed was 0.5 c.cm. per kilogramme of body weight. This dose was gradually increased and no cat exhibited any unusual signs at all until a dose of 1 c.cm. per kilogramme was reached. At this stage the cats exhibited giddiness, restlessness, drowsiness and a certain amount of unsteadiness in the hind limbs, but they completely recovered by the third day after treatment. Similar symptoms of varying severity, which depended on the size of the dose of tetrachlorethylene, were noted in all the cats until the dose of 4.5 c.cm. per kilogramme was reached, and they all recovered within three days. When doses of 5 c.cm. per kilogramme were reached all the cats died, usually within twenty-four hours of the drug being given, but one cat lingered in a semi-conscious state for nine days before death. The urine in the bladder of this animal contained a large amount of albumen, red blood cells, pus cells and casts. Larger doses than 5 c.cm. per kilogramme could not be given as the cats invariably vomited all or part of the dose every time this amount was exceeded.

We gave cats doses of 2 c.cm. and 3 c.cm. respectively of tetrachlorethylene per kilogramme of body weight, mixed with 4 c.cm. of 95 per cent alcohol, and this experiment was repeated twice. None of the cats showed any greater signs of intoxication than those in which it was given in milk or water. It seems clear that alcohol is not a contra-indication to the use of this drug.

Chandler and Chopra (1925) in their experiments with carbon tetrachloride on cats found that with such a small dose as 0.5 c.cm. per kilogramme, forty-five out of forty-nine cats died, and that with a dose of 0.25 c.cm. twenty-four out of twenty-seven died. These results alone indicate that the toxic effect of carbon tetrachloride is much greater than that of tetrachlorethylene.

According to Lamson, Robbins and Ward (1929) tetrachlorethylene has no destructive action on either the liver or kidneys, for they examined one hundred and sixteen animals including dogs, puppies, cats, rabbits and mice that had been given doses ranging from 0.3 c.cm. to 25 c.cm. per kilogramme without finding any change except a certain degree of fatty metamorphosis in the livers of cats and puppies, which they regard as a more or less normal condition for these animals. At the same time it should be noted that they killed cats and dogs with doses as small as 4 c.cm. per kilogramme though other dogs survived repeated dosing over long periods with 4 c.cm. per

kilogramme as well as still other dogs which were not killed by much larger single doses, so these results are not conclusive. In all cases they consider death was due to an over-dose of a hypnotic, though they do not explain how this occurred in adult dogs which they say do not absorb the drug from the intestine.

Dr. M. N. De, Professor of Pathology, Medical College, Calcutta, kindly examined sections of the livers and kidneys of several cats that had been given doses of tetrachlorethylene ranging from 1 c.cm. to 4.5 c.cm. per kilogramme and were killed within forty-eight hours of being given the drug. He also examined the organs of two cats that died within forty-eight hours of receiving doses of 5 c.cm. per kilogramme. The summary of his detailed report is as follows:—

Liver.—Congestion and fine fatty change, and a small amount of necrosis in one case.

Kidneys.—Congestion in the glomeruli with albuminous exudation, in the cats receiving the higher doses. Granular and fatty change in the tubular epithelium, the amount of damage being proportionate to the size of the dose.

From these results it seems clear that tetrachlorethylene has a definitely damaging action both on the liver and kidneys of cats, but comparison with the pathological findings of Chandler and Chopra (1926), on similar cats given carbon tetrachloride, indicates that the reaction of both these organs to the latter drug is so much more intense that the two drugs are not really comparable from this point of view. The much greater toxicity of carbon tetrachloride is still further emphasized when it is remembered that 0.5 c.cm. per kilogramme of this drug causes incomparably greater damage than does 5 c.cm. per kilogramme of tetrachlorethylene.

These experiments suggest that the effect of tetrachlorethylene on human beings in therapeutic doses will be negligible because 1 c.cm. per kilogramme in cats produces nothing more than a slight congestion in both liver and kidneys, and a dose of 3 or 4 c.cm. in the average Indian weighing sixty to seventy kilogrammes would at most represent only 0.15 c.cm. per kilogramme.

Conclusion

Tetrachlorethylene is much less toxic than carbon tetrachloride, and in therapeutic doses it causes no damage to the organs of otherwise healthy animals. An added advantage of tetrachlorethylene over carbon tetrachloride is that apparently it can be given in alcohol without increasing its toxicity.

A COLORIMETRIC METHOD FOR THE DETERMINATION OF MILK PROTEINS

By A. D. STEWART, M.B., F.R.C.S.E., D.P.H., D.T.M. & H.
LIEUTENANT-COLONEL, I.M.S., DIRECTOR

and

DURGA DAS MITRA, B.Sc., M.B., D.P.H.

(From the All-India Institute of Hygiene and Public Health, Calcutta)

THE method is based on comparing the blue colours developed by adding Folin's (1922) phenol reagent to different samples of milk and to a standard tyrosin solution. Of the different amino acids, only tyrosin and tryptophane (Folin and Looney, 1922) have been shown to give rise to a blue colour with this reagent; and tryptophane has been found to give rise to 58 per cent of the colour developed by an equal amount of tyrosin. We have determined colorimetrically the tyrosin equivalents of milk proteins for cow and buffalo milk, and these factors enable one to find out quickly the protein percentage of any sample of cow or buffalo milk.

The method is that followed by Greenberg (1929) for estimating the blood serum proteins. In the case of milk however, a turbidity and slight precipitation always result after the addition of the phenol reagent; this leads to slight modifications of technique.

By a series of colorimetric experiments and parallel determinations of the protein contents by Kjeldahl's method, we find that, on an average, 12 milligrammes of cow milk proteins and 15.2 milligrammes of buffalo milk proteins correspond respectively to 1 milligramme of tyrosin.

The following notes may be useful.

Reagents required :—

- (1) 5 N. NaOH.
- (2) Standard solution (0.02 per cent) of pure dry tyrosin in 0.1 N (approximately) HCl.
- (3) Folin's phenol reagent (Folin and Ciocalteu, 1927).
- (4) Whatman's filter paper, no. 5, size 15 centimetres.

For a series of milk samples take the corresponding number of marked measuring flasks. Arrange a similar number of marked filter funnels and beakers.

Maplestone, P. A., and Mukerji, A. K. (1929). Tetrachlorethylene in the Treatment of Hookworm Disease. *Indian Med. Gaz.*, Vol. LXIV, p. 424.

Rinse the pipettes twice with the sample after thoroughly shaking and mixing it, and pipette off 0.2 c.cm. of each sample in the case of cow's and buffalo's milk into the corresponding measuring flask and 4 c.cm. tyrosin solution into a separately marked flask. Add about 25 c.cm. of water to each, washing down all the traces of milk or tyrosin solution. Add 2 c.cm. of 5 N. NaOH to each, gently shake, add more water and again shake. Add 3 c.cm. of the phenol reagent and fill up to the mark as quickly as possible with water. Shake and keep for 10 minutes. Filter, and after 5 minutes of filtration begin to take colorimetric readings of different samples and complete all the readings within 15 minutes, i.e., from 15 minutes to within half an hour after the addition of the phenol reagent.

This time factor is important, as the maximum colour develops in about 15 minutes and after some time begins to fade.

When taking successive samples in the same colorimeter cup, rinse it twice with the solution under examination and wipe the colorimeter tube dry with a filter paper before immersing it into a fresh sample in the cup. The tyrosin standard is taken in the right-hand cup and fixed at 20, and the left-hand cup with the sample is adjusted till the colour matches, when the reading is taken.

Most of the experiments have been done in duplicate.

Samples should be fresh and examined colorimetrically preferably within 4 hours. Sour milk gives unreliable readings.

The protein content is calculated from the formula :—

$$\text{Protein percentage} = \frac{R}{X} \times T \times \frac{100}{S} \times \frac{F}{1,000}$$

where R = the arbitrary reading of the standard, i.e., 20.

X = the reading of the unknown.

T = tyrosin content in milligrammes of the standard, i.e., 0.8 in 4 c.cm. which we take.

S = the aliquot part of the milk used in c.cm.'s (0.2 c.cm. in this case).

F = the factor of tyrosin equivalence of the particular milk proteins (cow = 12, buffalo = 15.2).

Substituting actuals the formula reduces :—

$$\text{Protein percentage} = \frac{8 \times F}{X}$$

Taking the value of F for cows to be 12, and for buffaloes to be 15.2, this formula simplifies into :—

$$\text{Protein percentage} = \frac{96}{X} \text{ (for cow's) and } \frac{121.6}{X} \text{ (for buffalo's).}$$

The determination of 'F' for cow's milk.

TABLE I

Experiment number	Reading of the sample	Actual protein percentage by Kjeldahl's	F (calculated)
1	30.9	2.87	11.0

0.4 c.cm. milk was used for each colorimetric experiment.

TABLE V

Showing the protein percentage obtained by Kjeldahl's method and 'F' calculated on colorimetric readings and protein percentage

Experimental number	Reading of the sample	Protein percentage by Kjeldahl's	F (calculated)
1	22.8	1.79	10.18
2	33.26	1.4	11.6
3	23.0	2.68	15.4
4	28.2	2.01	14.38
5	37.5	1.4	13.1
6	27.5	1.96	13.47
7	23.1	2.5	14.4
8	20.6	2.9	14.93
9	24.4	2.4	14.6
10	26.6	2.1	13.96
11	25.4	1.8	11.43
12	24.1	2.1	12.65
13	23.8	2.2	12.09
14	26.4	2.2	14.5
15	17.8	2.6	11.57
16	20.8	1.97	11.2
17	24.0	2.5	15.0
18	28.8	1.8	12.96

Taking the average $F = \frac{237.47}{18} = 13.2$.

These samples came from women of various nationalities, of different ages, and different serial orders of pregnancies. They are all however from parturient women during the first week of lactation. The protein shows a wide variation in content. Lowenfeld, Widdows, Bond, and Taylor (1927) showed that the average percentage of protein in human milk varies considerably during lactation and the same authors found that the first month of lactation is a period during which the protein content falls from a high to a low percentage.

The calculated value of F in column 4 shows variations from 10.18 to 15, suggesting that the tyrosin and tryptophane content of human milk varies considerably in the first week of lactation. The calculated average for $F = 13.2$ is evidently not a close one and, as might be expected, the values obtained colorimetrically in table VI are not in close agreement with actual Kjeldahl findings. The method is therefore not suitable for determining the protein of human milk during the first week of lactation. We had no opportunities to examine human milk after the first week of lactation.

TABLE VI

Human milk

Showing colorimetric findings and actual protein percentage by Kjeldahl's method

Experiment number	Reading of the sample	Protein percentage by Kjeldahl's	Protein percentage by Kjeldahl's
1	21.0	2.5	2.1
2	26.0	2.0	1.6
3	26.9	2.0	1.7
4	24.2	5.0	4.7

The percentage calculated colorimetrically is that by volume, whereas Kjeldahl's determination gives percentage by weight. For practical

purposes this difference may be neglected as it is a difference only in the second place of decimals.

The percentage of milk proteins has been made a standard by the Madras Food Adulteration Act, 1918, and the validity of such a standard has been verified by Stewart and Chatterjee (1931) in Calcutta samples of milk. A simple method which can be completed within half an hour, with very small samples, either individually or in a series, may be useful.

In the case of known cow and buffalo milks reliable results can be obtained.

Our thanks are due to Lieut.-Col. Boyd, Principal of the Medical College Hospitals, and Lieut.-Col. Gow of the Eden Hospital for supplying samples of human milk from the Eden Hospital. We thank Mr. P. C. Mitra for supplying pure samples of cow's and buffalo's milk.

THE ACTION OF SOME SYNTHETIC ANTIMALARIAL REMEDIES ON THE UTERUS

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

J. C. GUPTA, M.B.

and

S. K. GANGULI, M.B.

Lady Tata Memorial Scholar

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

QUININE, until a few years ago, was considered to be the only effective remedy against malaria, and competent authorities expressed the opinion that it would be culpably trifling to use any other drug but quinine in the treatment of serious cases of malaria. The shortage of quinine supply during the war led to the production of a number of synthetic compounds for the treatment of malaria. Of these atebirin and plasmoquin have been shown to have a definite effect on the malarial parasites and have come to stay as powerful antimalarial agents. The work carried out in the School of Tropical Medicine, Calcutta, on the action of these drugs on the Indian strains of malaria parasites is in accord with findings obtained in other parts of the world.

Plasmoquin has been tried by a large number of workers, and in India, Napier, Butcher and Das Gupta (1932) used it with success in their field experiments. Atebrin has been found by Napier and Das Gupta (1932) to destroy the asexual stages of the malarial parasites especially of subtertian malaria. Chopra, Das Gupta and Sen (1933) have reported very favourably on the effectiveness of this compound against infections with the different strains of malarial parasites met with in Bengal. The antimalarial properties of tabetren and malarcan, two closely allied drugs, are under investigation and they show promise of being effective. These drugs are eupreine compounds and therefore cinchona derivatives.

In view of the favourable results obtained by these newer remedies and of the practical clinical importance of their oxytocic properties, it was decided to make a study of their action on the uterus. In this investigation direct observations were made on the action of these drugs on the movements of the isolated as well as the intact uteri of animals. The results obtained, although they may not be totally applicable in human beings, will give a fair indication as to the general action these drugs may be expected to produce in pregnant patients under treatment.

Plasmoquin is said to be n-diethyl-amino-isopropyl-8-amino-6-methyl-quinoline. The drug was synthesized by Professor Schulmann in the Bayer-Meister Lucius Laboratory, Elberfeld, and its antimalarial property confirmed by Roehl. Its action on the uterus as worked out at Elberfeld showed that in concentrations of 1 in 100,000 to 1 in 50,000, it produced no effect on the isolated uterus of the guinea-pig. In animal experiments *in situ*, the uterus did not respond to intravenous injections of 0.05 mgm. per kilogramme of body weight, but a response was obtained with doses twenty times this amount, which would be very toxic, the therapeutic dose being 0.3 mgm. per kilogramme of body weight. Clinically the effect of plasmoquin in pregnancy was studied by Jensen who treated successfully a pregnant woman suffering from malaria. Mazumdar (1929) stated that plasmoquin does not induce uterine contractions during pregnancy. Thakkar (1929) treated multiparæ in the third, fifth and eighth months of pregnancy with daily doses of 0.06 gm. of this drug. Manson-Bahr (1932) considered that plasmoquin is well tolerated by pregnant women and that they go on to full term and give birth to healthy children. Epstein (1933) states that, in therapeutic doses, plasmoquin has probably no action on the human uterus.

Atebrin is the dihydrochloride of an alkyl-amino-alkyl-amino-acridine derivative which was synthesized by Mietzsch and Mauss. It is a yellow powder soluble 1 in 14 of water, and has a very bitter taste. Apart from a

record by Manson-Bahr (1932) who treated successfully a pregnant woman, systematic study of its action on the uterus has not been made.

Malarean and tabetren are compounds of some stereo-isomeric bases of methyl eupreine with methyl acridine chloride and hydrochloric acid. The former was elaborated in the laboratory of pharmaceutical chemistry, Neugersdorf, and the latter by Messrs. Howard and Sons, London. Their effectiveness against malaria is being investigated by the senior author.

Experimental

Our experiments were carried out on the uteri of cats, rabbits and guinea-pigs. The action on the isolated uteri was studied in a Dale's bath containing Fleisch's solution at a temperature of 37.5°C. which had an hydrogen-ion concentration varying from 7.4 to 7.6, and through which oxygen was bubbled at an uniform rate. The action *in situ* was studied on cats by a modification of Barbour's method described by Chopra and David (1927).

As pure plasmoquin powder could not be obtained, tablets were employed in these experiments. One of these was dissolved in dilute hydrochloric acid, the acid was neutralized with caustic soda till precipitation just started, and in this way the drug was held in solution. For experiments with atebren, ampoules containing 1 c.cm. of the compound in 10 per cent solution were employed. The ampoules of malarean used in these experiments each contained 1 c.cm. of solution containing approximately 3 grains of the drug.

PLASMOQUIN. Isolated uterus.—In dilutions of 1 in 200,000 the automatic movements of the isolated uteri of cats and rabbits are accelerated and the tone of the muscle is increased. Higher dilutions such as 1 in 300,000 to 1 in 400,000 sometimes produce these results but often they are inert. Isolated uterus treated with successive concentrations of plasmoquin such as 1 in 200,000, 1 in 100,000, 1 in 50,000, reacted by showing a larger and larger acceleration of the automatic movements and an increase in the tone of the musculature as the strength was increased. With repeated doses no paralytic effects were obtained on the muscle. On the virgin uterus of the cat, effective concentrations varied from 1 in 200,000 to 1 in 100,000. In a few experiments with the pregnant uterus of rabbits, concentrations of 1 in 200,000 and more increased the tone of uterine movements, the response being greater as the pregnancy advanced. On the isolated uterus of the guinea-pig concentrations of 1 in 50,000 accelerated the rhythm and the amplitude of the contractions; no increase in the tone of the musculature was observed. Concentrations of 1 in 30,000 to 1 in 20,000 produced a decided increase in the tone.

Uterus in situ.—With doses of 2 mgm. per kilogramme, a slight increase in the tone and frequency of the contractions was observed; smaller doses produced no effect whatever. In multiparous cats doses of 1 mgm. per kilogramme increased the amplitude of individual contractions in some cases. After paralysis of the sympathetic nerve-endings with ergotoxin, the effect was still obtained showing that the drug probably acted on the musculature.

ATEBRIN. Isolated uterus.—On the non-pregnant isolated uterus of cats and rabbits concentrations of 1 in 100,000 to 1 in 50,000 were necessary to produce any appreciable increase in the amplitude of contractions,

and even with these concentrations the tone of the musculature was not materially altered. Gradually increasing concentrations of atebren after repeated washing of the uterus always produced a definite increase in the amplitude of contractions, thus showing no marked deleterious effect on the musculature. On the virgin uterus of the cat, concentrations of 1 in 20,000 to 1 in 10,000 were necessary to produce any definite response. With concentrations of 1 in 10,000 of the drug there was a definite increase in the tone and also acceleration of the rhythm. A few experiments were also performed on the pregnant uterus of rabbits; concentrations of 1 in 200,000 to 1 in 100,000 distinctly augmented the amplitude of the individual contractions, but no increase in tone was observed. On the isolated guinea-pig's uterus such high concentrations as 1 in 20,000 produced an increase in the amplitude of the contractions; 1 in 10,000 only increased the tone of the muscles.

Uterus in situ.—Doses from 1 to 2 mgm. per kilogramme of body weight, which fall within the therapeutic limit, had no effect whatever on the parous uterus. Increase in tone and acceleration of the rhythm was obtained with doses of 3 to 4 mgm. per kilogramme of body weight and a dosage of 5 mgm. per kilogramme increased both the tone and the rhythmic movements and produced a great fall of blood pressure. The effects on the virgin uterus were not materially different.

MALAREAN and TABETREN.—As already pointed out these are closely allied compounds and the effects produced on the uterus by both were more or less the same.

Isolated uterus.—Concentrations of 1 in 50,000 and less had no effect whatever. Stronger solutions such as 1 in 20,000 increased the tone in some cases; in others only the amplitude of the contractions was increased. On the virgin uterus of cats concentrations in the neighbourhood of 1 in 10,000 were necessary to obtain a definite response. On the pregnant uterus of rabbits acceleration of rhythm and slight rise in tone were observed with concentrations such as 1 in 30,000; with successive doses of higher strengths the uterus goes on to a state of tonic contraction. The rhythmic movements of the uterus of the guinea-pig were only increased with such concentrations as 1 in 5,000; marked increase in tone was obtained with 1 in 1,000.

Uterus in situ.—On the multiparous uterus, doses of 4 to 5 mgm. per kilogramme of body weight produced augmentation of individual contractions; increase in tone of the musculature was observed in some experiments. On the virgin uterus doses smaller than 6 to 7 mgm. per kilogramme had no effect whatever. After paralysis of the sympathetic nerve-endings with ergotoxin, the uterus still reacted in the same way.

QUININE.—In order to compare the effects of these drugs with quinine, a series of experiments were also performed at the same time with the bihydrochloride.

Isolated uterus.—Concentration of 1 in 200,000 in these experiments increased the amplitude of individual contractions of the parous uterus of the cat and the rabbit without any increase in tone; weaker concentrations, such as 1 in 300,000, produced no effect whatsoever. On the virgin uterus of the cat, concentrations varying from 1 in 150,000 to 1 in 100,000 produced a slight increase in both the tone and rhythmic movements; weaker concentrations, e.g., 1 in 200,000, increased the amplitude of individual contractions without enhancing the tone. The uterus of guinea-pigs definitely responded by accelerated contractions to concentrations of 1 in 20,000; concentrations in the neighbourhood of 1 in 10,000 markedly improved the tone.

Uterus in situ.—The smallest dose of quinine which could elicit a definite response in the virgin uterus of a cat was 5 to 6 mgm. per kilogramme of body weight; it definitely increased both the tone and amplitude of contractions. In a multiparous uterus doses between 3 to 4 mgm. per kilogramme produced a definite increase of tone and acceleration of the rhythmic movements. Smaller doses were absolutely ineffective.

Discussion

Acton and Chopra (1925) showed that with doses of 0.1 gm. of quinine by the mouth in cats weighing 2.5 kilogrammes, a concentration of 1 in 150,000 to 1 in 100,000 was reached in the blood in half an hour. An analysis of results obtained in these experiments shows that plasmoquin stimulates the contractions in concentrations of 1 in 200,000 or thereabouts in the isolated uterus. It would not be possible to attain such concentrations in the blood with the doses that are usually employed. Two mgm. per kilogramme given intravenously was the average smallest dose which increased the force of uterine contractions; this means that for an average individual 50 to 60 kilogrammes in weight, about 100 to 120 mgm. of plasmoquin will be necessary to produce any noticeable effect. The effective therapeutic dose of plasmoquin, however, never exceeds 20 mgm. for a single administration. It would therefore appear that in therapeutic doses plasmoquin will in all probability have no effect on the contractions of the human uterus gravid or otherwise.

Atebrin has been found to increase the amplitude of contractions of the isolated uterus only in concentrations in the neighbourhood of 1 in 50,000; improvement in tone and increase in the amplitude of contractions of the intact uterus was observed with intravenous doses of 4 mgm. per kilogramme of body weight. Such big doses invariably produced a fall of blood pressure which might possibly account for the effects produced on the uterus, but as these effects were also observed on the isolated uterus it is possible that the drug acts directly on the uterine muscle. Considering that the intravenous dose of atebrin, which would produce definite increase in uterine contractions, is 4 to 5 mgm. per kilogramme in the cat, the corresponding dose in human beings would work out at 240 to 300 mgm. But the effective therapeutic dose of atebrin never exceeds 100 mgm. at a time for an average adult man, so this falls within the range of safety.

With regard to malarcan and tabetren it has been observed that doses of 4 to 5 mgm. per kilogramme produce augmented contraction in the multiparous uterus while in the virgin uterus 6 mgm. or more have to be employed. This effect is not abolished even after paralysing the sympathetic nerve-endings with ergotoxin and therefore these preparations must act directly on the uterine muscle. The question arises whether these drugs will have any action on the human uterus in the doses that are usually given. Tabetren is prescribed in doses of 2 tablets of 3 grains each (approximately 400 mgm.) at a time, every four hours until 60 such tablets are given. Malarcan is prescribed every 2 hours so that the patient receives 12 tablets daily. For an average individual 250 to 300 mgm. of these drugs will be necessary to

produce any effect on the uterus and as the effective dose of both malarcan and tabetren is about 400 mgm. it is possible that even in therapeutic doses they may stimulate uterine contractions. Moreover as these remedies are to be given repeatedly six times a day the chances of cumulative action are greater.

If the effects produced by these drugs are compared with those produced by quinine, it will be observed that acceleration of uterine movements in the cat is possible by quinine in doses of 5 to 6 mgm. per kilogramme which is equivalent to 300 to 360 mgm. (about 5 grains) for an adult human being, 50 to 60 kilogrammes in weight. With the usual therapeutic doses in man therefore the margin of safety with plasmoquin and atebrin would appear to be very much greater than with quinine, malarcan and tabetren.

A perusal of the above results shows that the pregnant uterus is much more sensitive to the action of all these drugs than the virgin and parous uterus. Of all the drugs tested, plasmoquin and atebrin in therapeutic doses are least likely to produce any untoward effects on the pregnant uterus; malarcan and tabetren are more likely to stimulate uterine contractions if given in doses not much larger than therapeutic doses.

Summary and conclusions

1. The pregnant uterus is much more sensitive to the action of the antimalarial drugs than the non-pregnant uterus.

2. Our experiments on animals indicate that plasmoquin and atebrin, in therapeutic doses, are not likely to produce oxytocic action on the pregnant human uterus.

3. Malarcan and tabetren may produce increased contractions of the pregnant uterus in doses not very much larger than therapeutic doses. The chances of oxytocic action are increased in view of the fact that these preparations have to be given repeatedly every 2 or 3 hours throughout the course of treatment.

4. Large therapeutic doses of quinine are likely to increase the contractions of the pregnant uterus, and therefore in pregnancy small doses (e.g., 5 grains) repeated every 4 or 5 hours should be prescribed.

BILIARY LITHIASIS

Part I.

By M. S. KHERA, F.R.C.S. (Edin.)

Tarn Taran, Punjab

It is scarcely justifiable to consider biliary lithiasis apart from other gallbladder conditions, owing to the close association between the infective process and stone formation.

As in other surgical conditions, the treatment of biliary lithiasis must be based on an intimate understanding of the ætiological, anatomical, mechanical and pathological factors all considered together; it would be wrong to consider the mere existence of stones as a reason for removing the gallbladder without taking into account the cause of stone evolution. Yet this seems to be the basis of the present-day treatment of gallstones by either cholecystectomy, or the more palliative cholecystotomy. Nor is sufficient regard paid to the post-operative symptoms which frequently follow removal of the gallbladder.

Let us review in brief the ætiology, pathology and the anatomy of the biliary tract, with a view to the treatment of these factors as they arise.

Ætiological factors.—There are several classifications of gallstones, but we will consider them under two main headings: aseptic and septic.

Aseptic stones may be formed from pure cholesterol or pure bilirubin, or, rarely, biliverdin; or from a mixture of these, in any proportion. They all result from metabolic disturbance with an increase of the 'mother' pigment circulating in the blood. For example, the excessive cholesterol saturation of the blood during pregnancy leads to an excessive secretion of that salt by the liver, and this, passing in large quantities to the gallbladder, is precipitated either by crystallization, or because there is lack of the solvent salts in the bile. Once the cholesterol is precipitated, it tends to sediment to the fundus of the gallbladder by gravity, where it accumulates on account of the deficient outlet through the normal passage. If this precipitated cholesterol is removed from the gallbladder in the fine state of subdivision in which it is deposited when freshly formed in the biliary tract, no solidification occurs. For the solidification of the precipitate it is necessary that it should be retained sufficiently long, and this

may be brought about by any obstruction in either the cystic duct or Hartman's pouch. Aseptic stones are formed in the gallbladder itself as pure cholesterol or pure bilirubin stones, and there is now no doubt that such pure stones may be found also in the hepatic radicles of the biliary tract. This latter fact disposes of the main argument for the removal of the gallbladder for the cure of the source of their formation. Further, the common bile duct may be the seat of stricture following upon the impaction of previous stones, or an injury inflicted during the operation of cholecystectomy, and the same difficulties would follow.

The much-quoted statement that stones are a precursor of cancer is also an incomplete argument for removal of the gallbladder. We do not remove the urinary bladder or the kidney for stone; if the kidney is removed for stones it is because they recur there or because one kidney has sustained damage, and never because cancer is feared. But even if we accept the cancer-precursor idea, cholecystectomy leaves the site of stone impaction in the common bile duct, which could equally be the seat of cancer when irritated. It seems more reasonable to remove possible irritation at this site by the consideration of the other factors, removing by less drastic and more efficient technique the cause of stone formation or recurrence. Radically removing the site of stone formation finds a parallel in destroying a house as a prophylactic against cholera.

The solution lies in preventing the process of stone evolution in the body by dealing with the chemical, pathological and especially the mechanical factors in the biliary system, which are involved in stone formation.

Septic stones.—It is the pathology of these which renders the gallbladder such an important organ in diseased conditions. From the point of view of treatment it is important to understand their method of formation. It is true that chronic cholecystitis frequently leads to stone formation, just as stone formation leads to inflammation. The chronic infection itself is only a secondary factor in stone formation, the fundamental issue in stone formation being obstruction to the outward flow of bile from the gallbladder. If only infection with inflammation were present, the products of that inflammation—mucus or pus—would depend on whether the infection is mild or severe; normal drainage would ameliorate the trouble, and the gallbladder would become healthy. But should the outward flow of the inflammatory products be interfered with, obstruction would lead to a damming back of the contents of the gallbladder, followed by precipitation of the solid constituents. If relief of the obstruction is brought about in a short time, these precipitated contents will still pass out; but if the time of obstruction is prolonged, solidification will occur, and harder masses will form, fresh layers being

deposited on these concretions with each attack of obstruction. When the mass is too large to escape by the natural outlet, it assumes a more important rôle; it becomes impacted in Hartman's pouch. Recurring attacks of acute cholecystitis occur with accompanying complications, such as perforation of the bladder leading to peritonitis, abscess formation, or, in chronic cases, to a contracted bladder, its dense adhesions causing reflex symptoms in the stomach, attacks of colic, jaundice, etc. Hence it is clear that the most predominant feature of gallbladder disease is obstruction, any co-existing infection being secondary; therefore removal of the obstruction should be the chief aim in treatment, though this may not be complete, for there may still be obstruction in the ducts. The main trouble with stones is their relation to the ducts, yet the basis of the operation of cholecystectomy is to give most attention to the bladder, thus ignoring the condition of the rest of the biliary passages which is the most vital factor in stone pathology; and it omits consideration of the 'pressure-gauge' function of the bladder, regulating back pressure on the liver, and the pancreas. Instead of relieving the block, removal of the bladder further increases the internal pressure on the tracts. Though after effects may be mild, they often become severe, as in chronic dyspepsia, or there may be chronic, or even acute, pancreatitis because the regulator of internal pressure has been removed. After cholecystectomy if these mishaps are avoided, there may occur an obstruction in the common bile duct due to other causes, such as the pressure of enlarged glands around the ducts, cancer, and adhesions, and the patient may be incurably jaundiced because, with the bladder removed, no further surgical assistance is possible.

It is true that in the hands of the expert the mortality from cholecystectomy has been lower than from external drainage, the former being 1.3 per cent, the latter 1.5 per cent. Drainage, however, is resorted to only in the more severe cases. There is no doubt that drainage is by far the easier and safer procedure in very severe cases, and it is safer still when the disease is limited to the gallbladder or is of mild degree. In such cases, internal drainage would be of more advantage to the patient, so that when the disease is limited to the bladder and is mild, internal drainage might well be performed. If, however, the patient's condition will not justify a prolonged anæsthetic, simple external temporary drainage can be carried out in the first instance as in acute obstruction, followed later, if the condition permits, by internal anastomosis.

Surgical factors.—Some of the difficulties which may be encountered in the surgery of this condition are: obscuration of the operator's vision of the area by hæmorrhage, and especially the difficulty of obtaining a good view of the

hepatic artery and portal vein, the difficulties of dissection of dense adhesions around the neck of the bladder, and sometimes the impossibility of completing the removal of the contracted bladder from among the adhesions. Finally there is the even more frequent risk of a permanent fistula after the operation.

It is therefore considered that neither cholecystectomy nor the milder cholecystotomy is the operation of choice in gallstone disease. Dependent and internal drainage of the obstructed biliary and pancreatic passages must be carried out, no matter how advanced is the disease.

The loss of the function performed by the gallbladder because of its removal is an important matter, for it will naturally have certain effects on the biliary and pancreatic ducts. In health, the flow of bile is continuous from the liver to the gallbladder and it varies but little with the intake of food. The bladder receives all the bile as it is produced until the reflex from the duodenum causes relaxation of the sphincter of Oddi and allows it to flow into the gut. The presence of food in the alimentary tract causes this reflex, and when there is no food there is a damming back of both biliary and pancreatic secretions with resulting back pressure on these two organs, and this is sure to influence health, causing secondary changes such as cholangitis or pancreatitis.

After cholecystectomy there may occur such complications as biliary external fistula, intermittent or progressive jaundice because of stones having been overlooked at the operation, or having reformed in the biliary tract, or there may be stricture or kinking of the common bile duct, owing to fibrosis. There are also grave dangers associated with anatomical variations in the bladder and its surroundings. Flint says that in 65 per cent of cases there are abnormalities of the cystic duct and cystic artery, and often, therefore, the operator has difficulty from this cause.

Dependent drainage by means of cholecystenterostomy is advocated because of the following considerations:

Ætiological.—Aseptic stones are formed in the gallbladder and in the biliary radicles, and when they are retained long they increase in size, being steeped in concentrated bile which contains a high cholesterol and bilirubin content, maintained by the abnormal metabolism of the body. By removal of the gallbladder, the formation of stones within it would be eliminated of course, but formation in the ducts would not be affected. If the concentrated bile were drained efficiently from the gallbladder and from the ducts, this tendency to long retention would be frustrated; and since we know of no means of regulating the normal metabolism of cholesterol, etc., we could at least prevent stone recurrence by removing stagnation of bile before crystallization could

take place. Removal of the bladder constitutes no remedy for stone disease, at least in the case of aseptic stones. By dependent drainage of the bile from the whole biliary tract, its constant removal can be assured, and small stones which have been overlooked will be included in the downward drainage. Moreover, if a stone forms in the hepatic radicles it will follow one of the two courses indicated below. If a stone passes straight into the common bile duct, it may enter the duodenum, and even temporary impaction will produce no worse result than colic, and the portion of the biliary system above the obstruction would be efficiently drained, seeing there is an additional bypass, and the part below the obstruction would drain naturally. If the impaction occurs below the union of the pancreatic duct with the bile duct, there will be no evil consequences, for the whole biliary and pancreatic system will be drained into the intestinal tract.

Septic stones are a result of infection plus obstruction, and removal of the latter does away with the cause of septic stone formation. Dependent drainage and anastomosis secure this. Septic stones form primarily in the gallbladder, and are due to obstruction to the outlet at its neck, at the cystic duct by either stone impaction at Hartman's pouch or in the cystic duct by contraction, growth, or the swelling of the cystic duct. The ease with which the cystic duct may be obstructed is not surprising, as its lumen is not more than one-eighth of an inch in diameter. With efficient drainage at the base of the bladder it is difficult to see how stagnation or sedimentation can take place for long. But even if a small stone were formed, it could pass more comfortably through the larger aperture in obedience to gravity. The idea that cholecystitis leads to secondary stone formation in the gallbladder is countered by the fact that no septic nucleus would remain long enough to acquire the solidity or size necessary to render it pathological.

If a stone forms higher in the liver ducts, it will slip towards the more open duct lower down. After anastomosis, there is a choice of two courses for the stone; it may become impacted anywhere along the common duct, the position depending on other factors, and a similar course would be followed by any stone recurring and forming in the common bile duct. If firmly impacted it will block the natural path higher up, but with no adverse results, for the bile would be diverted along the artificial channel, and the pancreatic secretions will follow the normal course through the ampulla of Vater if the impaction is above the duct junction. Neither will there be any bad consequence if the impaction occurs at the ampulla, as the pancreatic secretions can flow along the alternative path, through the bladder into the duodenum.

Hence it is clear that cholecystenterostomy is not only a treatment for the stone disease present when a patient is operated upon, but is also a prophylactic measure against stone recurrence; the surgical treatment of any biliary condition is in my opinion not removal of the portion at fault, but effective drainage.

Pathological and mechanical factors.—The shape of the bladder, tapering as it does from Hartman's pouch towards the spirally coiled cystic duct only one-eighth of an inch in calibre, the common bile duct which is long and flaccid and passes among numerous glands so it is often pressed upon by them, the defective propulsive power from the gallbladder, and the very dependent position of the gallbladder fundus, which is aggravated in man's erect posture, are all against a satisfactory natural emptying of the organ, and so there are endless possibilities of obstruction. If the danger of recurrences mentioned above could be removed, gone would also be the nightmare of cancer formation.

Advantages of cholecystenterostomy.—If at the time of operation any irremovable obstruction were present, it would not be necessary to hazard a difficult dissection among dense adhesions, nor even an incision into the common bile duct in order to extract an impacted stone. The procedure advocated would be a safeguard against any future stricture obstruction. Even if the stone in the common duct were firmly impacted and irremovable, it would cause no harm, as it would be enveloped by fibrosis at the site of impaction, and the bile would pass through the artificial passage. Anastomosis could even be substituted for the difficult removal of a firmly impacted stone requiring retroduodenal interference. The same operation by a modified technique to be mentioned, is applicable to a contracted gallbladder where external drainage might be done. It also meets the risk connected with an irremovable fibrosed gallbladder which is a great source of focal infection and irritation tending towards cancer formation. It needs no dissection round the neck of the bladder, there is no danger to surrounding structures, and it is safer, easier, and freer from complications than other methods of operative interference.

Surgical and anatomical factors.—The gallbladder lies beneath the liver, with its most dependent part in contact with the first and second parts of the duodenum; it tapers to a fine spiral tube pointing upwards and backwards, which joins the common bile duct; thus the evacuation of bile is considerably hampered by gravity, and this is further aggravated by the valve-like effect of Hartman's pouch. Poor as it is under normal conditions, the exit of biliary contents is rendered more difficult when the bladder is diseased. In acute cholecystitis the predominant feature is obstruction, for without that no serious harm would follow.

Here again an emergency exit at the fundus is easily made under local anæsthesia, and will solve the difficulty; thus cholecystenterostomy in two stages can be applied to the relief of the acute disease with benefit equal to that already stated in relation to less acute forms.

The cholecystitis may be a primary affection leading to stone formation. There may be a chronic inflammation in the bladder walls, causing ill-health through septic absorption, or it may result in stone formation. There is a constant tonic effect on the bladder walls, which is aggravated by the chronically inflamed mucous membrane, and the walls remain in persistent spasm, as shown by the reflex pain at the bladder point on the abdominal surface.

With man in the erect posture, the cystic duct is already at a disadvantage in the matter of natural drainage, and in recumbency this is aggravated by the kinking of its walls caused by the weight of the bladder contents. A dependent bypass at the fundus will act as a gravity outlet for any stones would otherwise pass along the natural path.

The advantages of this operation are enhanced by its safety and simplicity, and by the elimination of the danger of damage to structures around the neck of the gallbladder. Any impacted stone which is present can be aspirated, spooned up, or milked up, as it will pass more easily back towards the dilated part of the duct above. If removal of the stone is not possible in this way, incision into the common bile duct over the site of impaction, and subsequent transverse suture can be performed. With a shrunken and fibrous gallbladder, buried in deep adhesions, drainage internally is easier and safer. In a difficult case with a small bladder the operation is best carried out in two stages. Cholecystenterostomy is also indicated in stone impaction in the common bile duct, partly as a cure of the condition, and partly as a precaution against stricture.

Simple external drainage often means fistula formation, with loss of bile, so that the patient must tolerate oral feeding with bile for the rest of his life. But if the external fistula were closed, it might mean a shorter and an inefficient drainage, leading to blockage and the aggravating factor of focal infection, which the external drainage might have temporarily relieved, and which had been ignored at the previous operation. If there is an internal fistula, the drainage after this operation would be most efficient and permanent. It is much easier than a reconstruction of the passages such as would be required in external drainage; also the focal infection could be permanently relieved.

THE CHOICE OF OPERATION IN DEPENDENT DRAINAGE OF GALLBLADDER

The relationship of the gallbladder to the pyloric end of the stomach, the first and second parts of the duodenum, the jejunum and the

colon renders anastomosis of the organ with one of them quite easy. The duodenum is not difficult to appose when there are no dense adhesions. The choice of the site of anastomosis of the gallbladder to the alimentary tract depends upon the advantages to the patient from the standpoint of safety and ultimate benefit.

With regard to anastomosis with the stomach, the part of that organ to consider is that lying in close apposition to the gallbladder, that is, the anterior surface towards the lesser curvature, near the pyloric end, just proximal to the pyloric vein, about one and a half inches from the sphincter of the pylorus. The main drawback in this anastomosis is that the alkaline biliary secretions tend to neutralize the acid gastric secretions, thus interfering with digestion in the stomach, and so inducing dyspeptic complications with biliary vomiting. But when the gastric acidity is abnormally high, as in the hypermotile stomach, this objection is not so important. The rarity of a secondary ulcer at the site of the anastomosis in gastroduodenostomy is due to the bile projected so near that site. The choice of the anastomosis of the gallbladder with the stomach should be based on a preliminary investigation of the gastric contents, the estimation of acidity, and radiological observations to ascertain the activity of the organ.

Where gastric analysis shows a low acidity of gastric contents, and the radiogram reveals a large dilated stomach, the ordinary treatment for gastric ulcer would be a posterior gastro-jejunostomy, even if there were associated gallbladder disease. Here recurrence of the ulcer would not be likely, and the existing gastric ulcer would heal, for the pathological condition is obstruction in the stomach, rather than acidity. Biliary anastomosis is not likely to be of assistance and some other site for apposition would have to be chosen. Where gastric acidity is low, with a dilated stomach, a gastro-jejunostomy would ordinarily be performed for an associated gastric ulcer and the gallbladder in such a case would not be apposed to the stomach. Anastomosis with the colon would lead to the digestive process being deprived of the bile, and would produce irritation of the colon causing frequent motions, as well as the great danger of infecting the biliary tract from the colonic contents. Anastomosis with the jejunum entails drawing up a loop of the small intestine in front of the duodenum and the stomach, thus introducing the troubles of kinking, torsion and looping of the jejunum, with obstruction. Also it diverts the bile too far down, thus increasing the liability to duodenal ulcer. Should a later operation be necessary for a gastric ulcer, a posterior gastro-enterostomy would be dangerous, on account of the great liability to post-operative obstruction. Hence the jejunum is not a suitable site for

(Continued at foot of opposite page).

CHRONIC AMŒBIC INFECTION AS A CAUSE OF ILL-HEALTH

By G. T. BURKE, M.D., F.R.C.P.

LIEUTENANT-COLONEL, I.M.S.

Professor of Medicine, University of Lucknow

It is impossible to practise for any length of time in this portion of the tropics without being struck by the number of patients suffering from general ill-health the cause of whose trouble has not been diagnosed. These patients drift from doctor to doctor, from one consultant to another, and in and out of hospital. In default of relief they provide a fruitful field for homœopaths, nature healers, compounders, indigenous practitioners, and quacks of all sorts, and they certainly do not add to the repute of western medicine. In many of them, owing to the combination of low fever, loss of weight and appetite, and, frequently, abdominal pain or discomfort, with or without diarrhœa, the diagnosis of tuberculosis is made, with its resultant load of anxiety and useless treatment; in others, often rightly, the condition is attributed to the degree of pyorrhœa present, which is so often found in Indians.

It is my object, in this note, to call attention to the third member of this triad—chronic infection with *Entamoeba histolytica*, or amœbiasis. With cases of frank dysentery, in its clinical sense, I shall not deal. Apart from the recognition of the infection by the character of the stools, the entamoeba is usually readily found. It is with cases of chronic infection that I am concerned.

A history of precedent dysentery, and, still more often, the absence of such history, I have found to be of very little value in diagnosis. Patients are forgetful; bowel derangements are common in India; the significance of 'dysentery' in the layman's mind is so varied. Even early attacks of amœbic dysentery may be characterized by diarrhœa only, without the obvious mucus and blood which leads to the label of

(Continued from previous page)

gallbladder anastomosis. With regard to anastomosis with the duodenum, this is the next easiest part with which to join the gallbladder. Surgically there may be difficulty in mobilizing the duodenum, but this is overcome by an incision parallel to its right side along the line of fusion of the four layers of the peritoneum covering the organ. Where there is difficulty owing to a contracted gallbladder, a T-shaped tube, with one limb in the bladder and the other in the duodenum, forms a temporary external drainage which later can be allowed to close while internal drainage continues. In a person with a normal stomach, anastomosis with the duodenum should be given preference, as it is more allied to the natural cure of the gallstone disease.

'dysentery'; therefore little reliance can be placed upon any but the most definitely positive history as suggesting the presence or absence of this infection.

Rogers (*Tropical Medicine*—Rogers and Megaw) gives, as indications of amœbic disease, a history of repeated relapses, thickening of the cæcum and ascending colon, tenderness due to local peritonitis, and hepatitis or enlargement of the liver. In the cases I am quoting below these points are well brought out and, in addition, I hope to be able to demonstrate that many cases of this infection fail to show even these signs, and some only suffer from general ill-health.

I have divided the cases into four groups:—

1. Cases with definite abdominal derangement, with signs of the involvement of upper colon or liver.

(a) Proved microscopically.

(b) Unproved.

2. Cases with abdominal symptoms, but with no definite objective signs.

3. Cases of general ill-health, without abdominal localization.

4. Cases under treatment for some other disease, found to be infected with *E. histolytica*.

The notes are abbreviated as much as possible.

Group 1.—These cases have the most definite symptoms, and should mostly be easily recognized. The first four were proved; in the other six the amœba could not be demonstrated, but it will be seen that their symptoms were in no way less suggestive than those of the others. Cases 9 and 10 had signs of liver involvement.

Case 1.—Hindu male. Previously treated in hospitals in America for 'ulcerative colitis'. For over a year suffering from attacks of looseness of stools with occasional blood and mucus, from almost constant discomfort and pain below the umbilicus, excessive weakness, and evening fever, latterly up to 101°F. Nothing objective found except general abdominal resistance and epigastric tenderness. In the third stool examined active *E. histolytica* were found. Thorough treatment by emetine resulted in disappearance of 'dysentery', fall of temperature, and general improvement.

Case 2.—Hindu male, aged 34, complains over a period of five months of fever, constipation, and right iliac pain. Previously diagnosed as pulmonary and also as abdominal tuberculosis, and treated by calcium and other therapy. Tender, gurgling, palpable cæcum, no enlargement of liver, no lung signs, fever to 99.5°F. daily. Sputum negative for tubercle bacilli, Wassermann reaction negative. Stools showed constant presence of cysts of *E. histolytica*. Treatment by emetine hydrochloride intramuscularly and emetine bismuth iodide orally resulted in disappearance of fever and much remission of symptoms.

Case 3.—Mohammedan female, aged 30. Chronic abdominal discomfort for six months with low fever for 3 months, and loss of weight. Was sent to hospital as a case of abdominal tuberculosis. Thickened gurgling cæcum, liver normal, stools showing dead amœbæ on each of three occasions. Treatment by emetine injections and emetine bismuth iodide produced considerable improvement, and fever settling down and pain being much relieved.

Case 4.—Hindu female. Chronic pain for one year in abdomen, especially right iliac fossa, occasional fever, chronic constipation, and loss of weight and

appetite. Abdomen soft and flabby with thickened and flatulent cæcum. Stools showed dead amœbæ. Treatment by emetine produced gradual but steady relief.

Case 5.—Mohammedan male, aged 19. Constipation for two years, constant abdominal discomfort for one year, attacks of frequent watery motions for four days (40 to 50 per day). Thickened cæcum present and right iliac tenderness. Stool examination repeatedly negative. Emetine hydrochloride, nine grains in one grain doses, was given before patient left hospital on account of relief of symptoms.

Case 6.—Hindu male, aged 24. Right lumbar pain of five years' duration, dull in character, lasting six or seven days at a time, loss of weight, appetite and strength. Previously diagnosed as abdominal tuberculosis and treated by twenty injections of tuberculin and twelve of Jacobsen's fluid, without result. No physical signs whatever except for a thickened cæcum, gurgling and tender on pressure. Stools negative. Emetine therapy was commenced, but patient left hospital too early for any result to be noted.

Case 7.—Hindu male, aged 23. For two years attacks of fever, alternating constipation and diarrhœa, loss of appetite and pain in right iliac, right hypochondriac, and umbilical regions. A thickened tender cæcum was found on palpation. Stool examinations negative. Treatment by emetine resulted in relief of symptoms.

Case 8.—Sikh male. Frequent attacks of diarrhœa over a period of six months, lasting two or three days, and recurring every fortnight or so. Suspected of being tuberculous. Stools yellowish with mucus at times but no blood. General abdominal discomfort with loss of appetite. Definitely thickened and tender cæcum, tenderness in right hypochondrium, and a palpable liver on deep breathing. Repeated stool examinations negative. On clinical diagnosis emetine treatment was instituted, and improvement was marked.

Case 9.—Hindu male, aged 30. Fever starting four months before, with enlarged and painful liver. Liver said to have been punctured and 'a bead of pus' obtained. He was treated with emetine. Anæmia, puffiness of face, liver enlarged to within 1 inch of umbilicus, and a localized œdema of the epigastric wall; slight ascites and right basal pulmonary crepitations. Stools loose and yellow, no mucus, two to three daily; repeated examinations failed to show amœbæ or cysts. Total white cell count 20,160 with 88 per cent polymorphonuclears. Treatment by emetine and emetine bismuth iodide, followed by anabin, produced a gradual but steady improvement, with diminution in size of liver and fall of white cell count to 8,000.

Case 10.—Hindu male. Fever for two months, accompanied by enlargement of liver, following an attack of 'clinical' dysentery three months back. The liver, which was enlarged by four finger-breadths, was firmer than is usually found in amœbic hepatitis. Total white cell count 12,080. No amœbæ or cysts were found in the stools. Wassermann reaction negative. Treatment by emetine was started, the fever subsided and the liver became less, but after eleven grains were given the patient left hospital.

Group 2.—These cases present definite abdominal symptoms but no physical signs. They varied in degree from frequently recurring dysentery to simple abdominal derangement with or without diarrhœa. In all save one microscopic examination of the stools gave a positive result.

Case 11.—Hindu female, aged 50. Attacks of frequency of stools, with passage of blood and mucus, and griping pain, over a period of one year. Physical examination negative except for tenderness on deep pressure in right hypochondrium. Stools loose containing blood and mucus and a few active *E. histolytica*. Treatment by emetine led to marked improvement.

Case 12.—Hindu female, aged 28. Diarrhœa for eight months, with abdominal pain and bouts of fever. Legs œdematous; debility and emaciation extreme. No local abdominal signs. Stools containing mucus and active

E. histolytica. Failed to react to treatment and died after three weeks.

Case 13.—Mohammedan male, aged 35. For six years almost weekly attacks of loose stools followed by constipation, with slight abdominal pain and much flatulence. During the hot season attacks are almost continuous. Only previous history 'typhoid fever' in 1924. Tenderness in umbilical and right iliac regions, but no thickening of the cæcum, and spleen and liver not palpable. Stools negative. On a clinical diagnosis of chronic amœbiasis he was given twelve grains emetine hydrochloride and left hospital much improved.

Case 14.—Hindu male, aged 30. Attacks of colic for two months and fever for one month. No physical signs except resistance and tenderness over gallbladder. No increase of blood cholesterol; no leucocytosis; polymorphonuclears 80 per cent. Visualization showed a long pendulous gallbladder but no stones. Stools showed large numbers of cysts of *E. histolytica*, *E. coli*, and a few of *I. butschlii*. Treatment by emetine hydrochloride and emetine bismuth iodide caused disappearance of cysts and subsidence of fever. He has remained well since.

Case 15.—Indian-Christian female, aged 24. Long-continued vague abdominal pain and discomfort and irregularity of bowels; slight fever for six weeks past; suspected of suffering from tuberculosis. Physical examination negative. Stools regular in time and character. Examination after administration of sodium sulphate showed first dead amœbæ and cysts, and subsequently active *E. histolytica*. Emetine treatment produced relief. The patient also suffered from attacks of lumbar pain, and radiologically the presence of a ureteral calculus was shown.

Case 16.—Mohammedan male, aged 20. Chronic constipation over a period of four years, with abdominal discomfort and loss of appetite, and recent fever with cough and cold. Two years previously found to be harbouring ankylostomes, *Hymenolepis nana* and *E. histolytica*, and had been treated with emetine. Thought he was suffering from tuberculosis. No physical signs in chest or abdomen. Stools contain a fair number of *E. histolytica* cysts and other protozoal parasites. Treatment by emetine and other amœbicidal drugs, over a period of a month and on a second admission three months later, when cysts were still found, produced considerable improvement.

Case 17.—Hindu male, aged 24. Constipation and loss of weight over a period of ten months. Cysts of *E. histolytica* had been found nine months before admission, and seven grains of emetine hydrochloride were given without result. No physical signs on examination. Stools, after several attempts, showed cysts of *E. histolytica*. Relief followed treatment.

Group 3.—The third group comprises cases where little is complained of except general ill-health, usually with fever of chronic type. These cases have often been diagnosed as tuberculosis, and there is little to suggest at first sight that they may be suffering from amœbiasis. Case 20 declared himself while in hospital by developing an acute attack.

Case 18.—Hindu male. Came to hospital suspected of pulmonary tuberculosis, suffering from fever for four months and loss of appetite and weight. Lung examinations, both clinical and radiographic, were negative. Wassermann reaction negative. No glandular enlargements. No physical signs. Stool examination showed active *E. histolytica*. There was no history of dysentery. Treatment by emetine produced relief of symptoms, the fever subsiding after the sixth injection.

Case 19.—Hindu male, aged 46. Admitted for fever up to 102°F. and cough lasting two months, and general weakness. Hæmoptysis of chocolate-coloured material for a few days a month before admission, and once later bright blood. No objective physical signs. One small specimen of blood expectorated suggested liver abscess material. Total white cell count only 8,800; liver not enlarged. Radiogram of chest showed calcified

glands only. Sputum and stools negative. Emetine and other amoebicidal drugs led to relief of symptoms and fall of fever. During injections he once complained of pain in the liver, and had a slight hæmoptysis, and on one occasion had diarrhoea.

Case 20.—Hindu male, aged 40. Loss of appetite and slight fever for over four months, and loss of weight and anæmia. Suggestion of tuberculosis. No physical signs found except severe anæmia with total red cells 3,500,000 and a blood picture of secondary anæmia. In hospital developed dysenteric motions containing large numbers of *E. histolytica*. In spite of stimulant and anti-amoebic treatment his condition gradually became worse and he died after seven weeks.

Case 21.—Anglo-Indian female. Admitted for low fever and loss of appetite; no other symptoms whatever. Lungs clear clinically and radiographically. Total white cell count 11,000 with normal differential count; night and day blood negative; urine sterile. No abdominal or bowel symptoms, but examination of stools showed active *E. histolytica*. Treatment by emetine led to subsidence of fever, and gradual improvement of health, with increase of weight.

Case 22.—Mohammedan male, aged 35. Low evening fever and loss of weight over three months. A year before had been operated on for fistula in ano. The suggestion was that he was suffering from tuberculosis, but there was no history of cough or hæmoptysis, nor of dysentery or any abdominal complaint, and there were no physical signs, abdominal or pulmonary. Stool examination showed active *E. histolytica*. Treatment by emetine was bringing some relief when patient left hospital for private reasons.

Group 4.—This case illustrates the finding of *E. histolytica* in a patient under treatment for another complaint. In a country like India, where multiple infections are common, such a possibility must never be lost sight of.

Case 23.—Hindu male, aged 24. In hospital for treatment of hookworm infection with severe anæmia. After several treatments with thymol and removal of a number of ankylostomes he developed dysenteric motions, found to contain active *E. histolytica*. Treatment by emetine injections and subsequent emetine bismuth iodide produced rapid relief.

With the above cases I hope to have illustrated the prevalence of chronic amoebiasis even where it may not be at once suspected. The importance of realizing this fact I need not emphasize. Many of these patients believe themselves to be suffering from tuberculosis, usually of the abdominal type, and it is very common indeed to find that they have undergone various treatments directed against that infection. To rescue even a proportion from the mental worry, useless expense, and waste of time involved is itself an achievement.

It is not only practitioners in the tropics who have thus to be on their guard: those who are practising in temperate regions to which patients from the tropics retire or go on leave may also be confronted with the same problem, though their main interest lies in the fact that the symptoms complained of by these sufferers suggest the diagnosis, not infrequently, of appendicitis, and Rogers (*Recent Advances in Tropical Medicine*) points out the frequency with which chronic dysentery patients appearing before the Medical Board of the India Office have had their appendices removed without any permanent benefit.

BRONCHOSCOPY : ITS USEFULNESS IN INDIA

By E. H. EVANS, B.A., M.D.

St. Luke's Hospital, Vengurla

BRONCHOSCOPY is the art of examining the trachea and bronchial tree by looking through a rigid tube which serves as a speculum. Laryngoscopy and œsophagoscopy are terms which are applied to the similar examination of the larynx and œsophagus, respectively. These procedures collectively are commonly included in the general term 'bronchoscopy'.

This specialty has been mainly built up during the past twenty-eight years by Dr. Chevalier Jackson and his associates in Philadelphia. At first bronchoscopy was used principally for the removal of foreign bodies from the air and food passages, and sometimes the results were very spectacular. One operation requiring the utmost skill was the removal of four safety pins from the œsophagus of a small child. These safety pins were open and interlocked and the points of all were pointing upward. The great variety of foreign bodies removed includes coins, buttons, tacks of various kinds, bone or bone fragments, beans and other kinds of seeds, dry cell (battery) caps, dentures, needles and various kinds of pins, in fact almost anything that an adult or child is likely to put into the mouth.

At present, however, the foreign body cases constitute less than 2 per cent of all the cases in the Philadelphia bronchoscopic clinics. This is not because foreign body cases are fewer. They are indeed more numerous, but the field of bronchoscopy has so greatly widened. Some of the other uses of bronchoscopy are: aspiration of lung abscesses, aspiration of bronchiectatic cavities, cure of 'post-operative pneumonia', which is really atelectasis caused by the obstruction of a bronchus by tenacious mucus, diagnosis of lung tumours, early diagnosis and treatment of cancer and other tumours of the larynx or œsophagus, diagnosis and treatment of stricture and ulcer of the œsophagus, as well as the diagnosis and treatment of cardiospasm, 'lung mapping', by injecting

(Continued from previous column)

I have come to look upon the presence of right iliac symptoms, much short of signs such as Rogers cites, as suggestions of chronic amoebiasis even in the complete absence of clinical dysentery or of diarrhoea. Many of these patients, far from complaining of looseness of the bowels, emphasize the presence and frequency of constipation and may have attributed any diarrhoea to purgatives they have taken in consequence.

I am indebted to Dr. P. N. Wahi, my late house physician, for most of the case notes. The pathological examinations were carried out in the pathology department of King George's Medical College.

lipiodol through the bronchoscope into the exact portion of the lung where it is wanted and then taking an x-ray plate to visualize the extent of the lesion. This last procedure is especially valuable before attempting the more radical operations of thoracic surgery such as thoracoplasty and lobectomy.

The technique of performing a bronchoscopy is briefly as follows:—The patient lies on the operating table in the dorsal position, the head and shoulders being supported by the first assistant who sits at the patient's right. The first assistant holds the head in such a manner that the neck is sharply flexed at the seventh cervical vertebra and sharply extended at the occipito-atloid joint. He also keeps the mouth open by means of a special mouth gag or 'bite-block'. A second assistant keeps the shoulders well down on a level with the table. With the patient in such a position the operator can insert the laryngoscopic speculum or laryngoscope, lift the epiglottis forward and obtain a direct view of the larynx and vocal cords. He then passes the tubular bronchoscope through the laryngoscope and insinuates it between the vocal cords and well into the trachea. The heavy laryngoscope is then removed and the bronchial tree is leisurely and thoroughly explored, the patient breathing through and around the bronchoscope. The direction of the bronchoscope can be varied at will by directing the first assistant to change the direction of the head of the patient. When a foreign body is encountered, a long and very delicate forceps is passed through the bronchoscope and the foreign body is grasped while in view of the operator, and removed. In the early days bronchoscopy was attended with considerable mortality. But now the development of technique and team work, together with the elimination of general anaesthesia, have practically done away with deaths.

General anaesthesia is never used in the Chevalier Jackson bronchoscopic clinics. No anaesthesia whatever is given to children under 10 years of age. For bronchoscopies in adults 4 per cent cocaine is applied to the pyriform sinuses and 1 c.cm. of 4 per cent cocaine is advantageously injected intratracheally. For oesophagoscopies 10-15 drops of cocaine hydrochloride 4 per cent solution are placed on the base of the tongue and swallowed. For bronchoscopies in adults a preliminary hypodermic of morphine sulphate $\frac{1}{4}$ to $\frac{3}{8}$ grain and 1/150 grain of scopolamine is given one hour before the patient goes to the operating room. No food or water is given for five hours prior to any endoscopic procedure. Rectal anaesthesia may advantageously be given in the case of very nervous and apprehensive patients.

It recently has been my privilege, after taking Dr. Jackson's personal course in bronchoscopy, to serve for three months as an assistant both to Dr. Chevalier Jackson and to Dr. Louis H. Clerf. During that time it was my good fortune

to perform 103 bronchoscopies and 5 oesophagoscopies.

Since returning to Vengurla from furlough there have been a rather limited number of bronchoscopic procedures, 14 in all. There have been no mortalities. The patients are usually up and about on the same day, or the day following the procedure. Three cases are reported as follows:—

Case 1.—A case where oesophagoscopy was of distinct advantage was that of J. D. M., male, 52 years old, emaciated, who, for seven months, had vomited all solid food five minutes after swallowing it. Liquids were swallowed very slowly and with increasing difficulty. X-ray examination showed an obstruction in the lower third of the oesophagus with considerable dilatation above the stricture. The oesophagoscope disclosed a constriction about 16 inches from the teeth with an irregular gray, nodular object the size of a pea fitting into the constriction and evidently acting like a ball-valve in retarding the passage of food. It was evidently made up of decomposed and adherent food particles for when removed it broke up like a dried blood clot. Also at the constriction, a small sub-epithelial tumour-like body protruded into the lumen and evidently aided in the valve action. The oesophagoscope was passed beyond the constriction however, and into the stomach.

The ordinary oesophageal bougies were passed after several days but met with an obstruction about 16 inches from the teeth. Had they been forced down they might have perforated the oesophagus and caused a fatal mediastinitis. However the patient was directed to swallow, slowly, a strong linen thread 15 feet long. On the end of this was threaded the perforated olive tip of a hydrostatic oesophageal dilator. With the thread as a guide the tip of the dilator readily passed the obstruction and then was inflated to 10 pounds pressure for 5 minutes.

Thereafter the patient was encouraged to take, gradually, solid food and he left the hospital eight pounds heavier, an exceedingly grateful patient. He denied syphilis and his Kahn test was only + +, yet we pushed anti-leucic therapy and believe this to have been a case of gumma of the oesophagus. Had it not been for the oesophagoscope, he probably would have suffered the misery of gastrostomy.

Case 2.—R. R., a weak old man of 58 years with terrible dyspnoea, was admitted on 10th November, 1931. He stated that he had had difficulty in breathing since an operation on the right nostril one year ago. The right nostril was stenosed and on auscultation over the chest a flapping sound was heard at the beginning of each wheezing inspiration. Mirror laryngoscopy revealed a paralysed epiglottis which flapped down over the entrance to the larynx and almost prohibited the entrance of air.

A similar picture, though inverted, was seen by direct vision, using the Jackson laryngoscope. Through this tubular instrument was passed the laryngeal cup forceps, and the epiglottis was partially amputated by cutting off its edge. By this procedure the dyspnoea was lessened, but when the epiglottis was raised upward it was seen that the entire larynx was in a softened paralysed state so that on each inspiration its walls and the inter-arytenoid tissue collapsed, closing the lumen almost completely. The unfortunate old man refused tracheotomy and continued to breathe laboriously for several days; then he became unconscious from respiratory collapse. He stopped breathing on the operating table while tracheotomy was being performed and was revived with difficulty. He gained strength rapidly however and was a most grateful patient when he left the hospital on 16th March, 1932, wearing his tracheotomy tube.

Case 3.—S. D. S., a young woman of 19 years, had hæmoptysis, occasional and slight, for nine months

FÆCAL BACTERIA IN BENGAL AS INDICATORS OF SEWAGE CONTAMINATION OF WATER: A PRELIMINARY STUDY

By B. R. BRAHMACHARI, D.P.H.

Director of Bengal Public Health Laboratory
and

G. N. SEN, M.B., D.T.M.

(Read at the Indian Science Congress, 1933)

THE method which we follow in the bacteriological analysis of water in Bengal was based on that used by Col. Clemesha in the study of flora of the human faeces in Madras. As the diet of the people of the Presidency of Bengal differs somewhat from that of the people of Madras, one might suspect the faecal flora of the two provinces to be not quite the same. A detailed bacteriological examination of the stools of this province may prove to be of help in assaying the import of these bacilli, individually and in association, in interpretation of the result of analysis of water, so we have examined the stools of twenty-five persons of this province as a preliminary measure.

Colon bacilli in Bengal faeces:—In his research in Madras, Col. Clemesha examined 751 colonies of lactose fermenters from forty-three stools; we examined 734 colonies. They were identified by the fermentation tests on saccharose, dulcitate and adonite, by the alkali-red reaction of Voges and Proskauer and by the indol reaction; to these we added the citrate utilization test of Koser. They of course all fermented lactose with production of gas, that is, were members of the *Bacterium coli* group. The different species of *bacterium* found in these stools are shown in the table on the next page.

(1) *Species of bacterium*.—Clemesha found 22 different bacilli in Madras, we also found 22 in the Bengal stools examined.

(Continued from previous page)

preceding admission to this hospital. She had been treated in a sanatorium with some relief, but had had several small hæmorrhages during the month before she came to us. There was slight cough but no fever. There were five examinations of the sputum during her stay of three months in this hospital. All these examinations were negative for tubercle bacilli, but on two occasions spirilla were found. Frequent physical examinations of the lungs were uniformly negative. A bronchoscopy was done in the hope of finding a bleeding point. None was found and the bronchial mucous membrane appeared normal. Swabs were taken from the bronchial mucous membrane but no tubercle bacilli nor spirilla were found. However, after the bronchoscopy there were no more hæmorrhages. The patient was discharged apparently cured after twelve days and we believe that in case of a recurrence of hæmoptysis she would probably have returned to us, since she lives near by.

The cases to date have been comparatively few but, from their variety and from the results obtained, we feel that there is a distinct field of usefulness for bronchoscopy in India.

(a) Fourteen of these are common to the two provinces, viz, *Bact. coli commune*, *Bact. neapolitanum*, no. 101, *Bact. cosecoroba*, no. 75, *Bact. rhinoscleroma pneumoniae*, *Bact. vesiculosum*, *Bact. coli mutabile*, *Bact. lactis aerogenes*, *Bact. acidi lactici*, *Bact. cloacæ*, and the rarer ones *Bact. levans*, and nos. 33 and 67.

(b) Eight were present in the Bengal faeces but not in Madras, viz, nos. 111, 74, 104, 99, 36, *Bact. oxytocum* and nos. 97 and 66.

(c) Eight were absent in the Bengal faeces though found in Madras, viz, nos. 6, 9, 10, 37, 38, 39, 70 and 105.

(2) *Relative prevalence*.—In both the provinces, none of the species were present constantly in all the faeces. But while the striking feature in Madras was the continual steady presence of *B. vesiculosum* and *mutabile*, *B. cosecoroba* and to a less extent *B. coli commune*, in Bengal *B. neapolitanum* is decidedly at the top of the list, being present in 80 per cent of the stools and giving 17.8 per cent of the total number of colonies. This is followed by *B. coli commune*, *B. cosecoroba* and *B. vesiculosum*, the first of which was present in 72 and the other two each in 50 per cent of the faeces and they gave respectively 10.2, 9.6 and 9.5 per cent of the total colonies. Though giving about half these number of colonies or less, no. 101 was found in 64 per cent of the faeces, no. 75 and *B. lactis aerogenes* each in 48 per cent and *B. rhinoscleroma pneumoniae* and *B. acidi lactici* in 40 per cent.

Periodical variation, if present, cannot possibly be detected from examination of some 25 or even one hundred colonies from each stool, as it contains from 100 to 1,000 million colon bacilli and more per gramme, of at least 22 different kinds and perhaps others which were missed on account of the paucity of the number of colonies examined.

The members of class I of Clemesha in the Madras stools were *B. coli commune*, and nos. 39 and 70. In Bengal we also found *B. coli commune*. Besides this, the only other members of the class I found here were no. 36, *B. oxytocum*, *B. perniciosum* and no. 97; the first two were present only in 12 per cent of the faeces and the last one in 4 per cent. Taking these three together, the number of their colonies were about 4 per cent of the total.

Class II is represented in the Bengal flora by *B. neapolitanum*, no. 101, *B. cosecoroba*, *B. rhinoscleroma pneumoniae*, *B. lactis aerogenes*, *B. acidi lactici* and no. 33, the first eight in the table very liberally, being found in 40 to 80 per cent of the faeces and together giving about 50 per cent of the colonies.

Significance of these bacilli in water as indicators of recent sewage contamination:—

(a) In about 75 per cent of cases of recent sewage contamination of water, it appears from the above that we may expect the presence of *B. coli commune* and perhaps some of the other

-	--------	--	---------	--	--------	--	---------	--	---------	--	--------	--	--------	--	---------	--	--------	--	--------	--	---------	--	--------	--	---------	--	---------	--	--------	--	--------	--	---------	--	--------	--	--------	--	---------	--	--------	--	---------	--	---------	--	--------	--	--------	--	---------	--	--------	--	--------	--	---------	--	--------	--	---------	--	---------	--	--------	--	--------	--	---------	--	--------	--	--------	--	---------	--	--------	--	---------	--	---------	--	--------	--	--------	--	---------	--	--------	--	--------	--	---------	--	--------	--	---------	--	---------	--	--------	--	--------	--	---------	--	--------	--	--------	--	---------	--	--------	--	---------	--	---------	--	--------	--	--------	--	---------	--	--------	--	--------	--	------	--

three members of class I also. We found among the 25 colonies from one of the stools, two of the *B. oxytoca* as the only such indicator, there being none of the *B. coli commune* group among them. But in six of these stools, that is in 24 per cent, we had none of these class I bacilli. Thus if we take the presence of bacilli of class I as the test for recent pollution of water, 24 per cent of polluted water will pass this test.

(b) In the stools nos. 1 and 12 containing no bacilli of class I, *B. lactis aerogenes* with only one other member of the class II occurred in association with a larger number of species of class III. In the case of stool no. 1 the colonies of *B. lactis aerogenes* were only three and those of the other class II bacillus, *B. neapolitanum*, two out of the total number of 48 bacilli examined, while *B. no. 74* gave 17 and *B. cloacae*, 13. So if the water inoculated with this sewage were further diluted and only 10 colonies were examined, as is usual in practice, the only species found would have been *B. no. 74* and *B. cloacae* either without any bacillus of the class II or with only one or two colonies of these two classes. In the former case the bacilli would have been passed over in the case of surface waters, according to the Clemesha standard, and, in the latter case, the contamination would have been regarded as sufficiently advanced in purification to be passable for drinking. In the case of stool no. 12 the class II bacilli, *B. lactis aerogenes* and *B. acidi lactici* formed fourteen out of the 25 colonies; with dilution and examination of only 10 colonies, the contaminated water would also have been passed as of fair standard of purity. So with Bengal faeces even the criterion of mixture of bacilli of classes II and III may be misleading.

(c) As to the Koser's citrate utilization test developed since the days of Clemesha, in stool no. 1, 46 out of 48 colonies were citrate positive, the two exceptions being of *B. vesiculosus* two colonies of which utilized the citrate. All the 44 colonies of another stool not entered in the list acted on the citrate; and only one out of the 22 colonies of another such stool was citrate negative. Therefore, especially when we limit ourselves to only 10 colonies in our practical work, it may be quite possible to get only citrate utilizers in water recently polluted with human faeces.

Conclusion.—Absence of any colon bacilli in 60 c.cm. of water may show it to be free from sewage contamination and their absence in not less than 10 c.cm. may be a fair standard of purity for surface waters. But when they are present in any water in larger numbers, it is questionable, in face of the above facts, if such water can be passed for drinking, even if the class I members are absent or if a few of the class III ones are alone present or if a class II

one like *B. lactis aerogenes* predominates, associated perhaps with one or two other bacilli of these two classes. Clemesha had to relax the quantitative standards for surface waters because in his time few waters of the waterworks in Madras would pass them. The qualitative tests in question, relying on particular members of the colon groups or combinations of them as indicators of the pollution, were introduced by him as a necessary safeguard in such cases. Happily of late, bleaching-powder and other preparations are coming increasingly into use for final purification of the water, and appliances like chlorinators are making it easy to control the dose of the chlorine so as not to leave any of it to reach the consumers though it is sufficient to purify the water. Having regard to all these facts, may we not tighten the screw and insist on a higher standard of water purity on the quantitative basis?

A Mirror of Hospital Practice

SPLENECTOMY FOR SPLENIC CYST

By F. C. FRASER

LIEUTENANT-COLONEL, I.M.S.

Distriet Medical Officer, Coimbatore

THE patient, a female aged 16 years, had noticed a swelling in the upper part of the abdomen for about two months; of late it had increased rather rapidly in size.

Examination revealed a large cystic swelling filling the left hypochondriac, epigastric, lumbar and umbilical regions. It was smooth and rounded in outline and did not cross the middle line; it was completely dull on percussion. Splenic tumour or pancreatic cyst was thought of, especially the latter as no notches could be felt on the border. Two weeks elapsed before an opportunity offered for operation and during this time the tumour grew rapidly, crossed the middle line and now filled the opposite (right) epigastric and umbilical regions. A skiagram after a bismuth meal taken at this time revealed the stomach lying in the right hypochondriac region, having been pushed across by the tumour.

The abdomen was opened through a paramedian incision in the left lateral line extending from the ribs to the umbilicus, and more room was obtained by a second incision running outwards in the transpyloric plane. An enormous cyst was found with a comparatively small spleen attached to its left border. Portions of the cyst were translucent and through one of these clear places, the cyst was tapped and about seven pints of clear fluid evacuated. As the cyst collapsed, the stomach came across to its correct position and it was then seen that the viscus was attached to the cyst by the gastro-splenic omentum, the included vessels being very short and plunging almost directly into the cyst. These vessels, the vasa brevia and the left gastro-epiploic, were ligatured with some difficulty owing to

the small space available, but a clamp put on to the adjacent collapsed cyst helped considerably. The cyst and spleen were then delivered from the abdomen and the splenic vessels secured and the lienorenal ligament divided—the latter being remarkably thickened and tough. Three small accessory spleens were left *in situ*, one was half an inch in diameter, the other two were only the size of peas. Doubtless they would grow in time and take on the function of the original organ.

The wound healed by first intention and the patient exhibited no signs of shock or any other untoward symptoms. She left the hospital two weeks later and is now, after a year, perfectly fit and healthy.

A CASE OF PURPURA RHEUMATICA (SCHONLEIN'S DISEASE)

By P. K. BANERJEE, M.B.

Ajmeer Road, Agra

THE patient was a Hindu female of the bania caste, and her general appearance was dull, pale and extremely emaciated. Her temperature was 99.8°F. , pulse—140, feeble and thready, and respiration—22 per minute.

Punctate petechial hæmorrhages, attended with slight temperature, appeared on the third day after the onset of menstruation; the hæmorrhagic spots were distributed all over her body and face, being more pronounced on the extremities, especially on the inner sides of the thighs. Next day bleeding from the mouth began, and she passed urine intimately mixed with blood. The rash was level with the skin, and when I saw her the colour had changed from pink to dark purple. The mouth was very sore and the gums were inflamed, hæmorrhagic patches being present on them. The tonsils were very slightly inflamed. The bleeding from the mouth was apparently from the inflamed gums. The throat was congested; lungs normal. The heart revealed a loud hæmic murmur in the pulmonary area, which may be attributed to the anæmia, the hæmoglobin value being 46 per cent. No gastro-intestinal symptoms were present. The bowels were constipated. The spleen was palpable and very tender on pressure. Vaginal examination revealed the cervix to be completely closed, so I concluded the bleeding was only from the urinary channels, either from the bladder or from the kidneys.

History of previous illness was negligible. There was no history of hæmophilia in the family.

The following treatment was adopted: Normal horse-serum, 10 cubic centimetres, was injected intramuscularly, followed by horse-serum tablets by mouth. The bladder was washed with hot boric lotion, followed by a hot lysol vaginal douche. Neotropin tablets were prescribed orally, *ter in die* and the mouth was swabbed with hexylresorcinol solution 1 in 1,000.

Next morning the general condition of the patient was better. Bleeding from the gums had completely stopped, but the urine was still mixed with blood, though it was less in amount. The temperature had gone up to 100.8°F. , and she started complaining of pains in the large joints. The same treatment was continued, except that the patient was put on salicylates 10 grains *ter in die*, as it was suspected that the purpura was of rheumatic origin. The salicylates had a dramatic effect and stopped the bleeding within the next 24 hours and the temperature touched normal, proving the case to be of rheumatic diathesis. The rash gradually disappeared within the next four days.

[Note.—The inflamed, sore gums which were the most prominent signs in the case suggest to us that scurvy was much more probably the condition present. There is also probably a connection between the injection of horse-serum and the onset of joint pains with a slight rise of temperature. We doubt the justification of basing a diagnosis of acute rheumatism on the effect produced by three 10-grain doses of sodium salicylate.

Also the claim that the salicylate stopped the hæmorrhage appears somewhat exaggerated in view of the fact that the horse-serum had already stopped the bleeding from the gums and had greatly reduced that from the bladder.—EDITOR, I. M. G.]

A VESICAL CALCULUS OF UNUSUAL SIZE

By B. N. KHANNA

House Surgeon, State Hospital, Junagad

A HINDU male, aged 43 years, was admitted into this hospital on 14th March, 1933, with symptoms of stone in the bladder. The bladder was sounded, and it was found that the stone was too big for litholapaxy. The alternative method of suprapubic lithotomy was suggested to the patient, but he refused operation and was discharged on the 20th March, 1933.

He was admitted again on the 11th May, 1933, and this time, was willing to have the suprapubic operation done. The patient was prepared in the usual way, and the operation was performed under chloroform anaesthesia by Captain P. T. Majumdar. An incision about three inches long was made from the top of symphysis pubis upwards in the middle line. The lower part of linea alba having been divided, the extraperitoneal tissues were separated. Two lateral sutures were passed through the bladder wall, and the already filled bladder was incised longitudinally. The gloved finger being put in, the enormous size of the stone was realized, and it was found to almost fill the bladder. In attempting to take it out, the thick crust of the stone was separated, and was removed piecemeal. The body of the stone was taken out later. The bladder wall and skin incision were closed and a *ter* inserted. The patient made an

The weight of the stone was 5 ounces 1 drachm.

A LARGE FIBRO-ADENOMA OF NECK

By BISHAMBAR NATH SIBAL, M.B., B.S.

In-Charge Civil Hospital, Mardan

A. S., a Pathan aged 60, presented himself at the out-patient department of the civil hospital,

Fig. 1.

Mardan, on 22nd February, 1933, having walked from Sakarga in Tribal Territory, a distance of

300 miles, to seek treatment for a large tumour growing from the right side of his neck.

The tumour, which by its weight and size was obviously causing distress, was supported by a cloth suspended from the patient's head. It was hard and nodular, freely movable over the subjacent tissues and had an ill-defined pedicle. It extended from the tragus of the right ear to within one inch of the symphysis menti (figure 1). Patient stated that he noticed a small lump in the skin over his lower jaw about the time his beard began to grow, over 40 years ago, and since then this lump had been gradually increasing in size. When asked why he had waited so long before seeking relief, he explained that he had no desire to risk his life by undergoing a surgical operation while in the flower of his youth, but that now being a grandsire and in the winter of his years he was prepared to take any risk to be rid of the discomfort of the tumour.

Patient was operated upon on 27th February, 1933. An elliptical incision was made round the base of the tumour which was easily removed *en masse*. The blood-vessels in the pedicle having been secured and ligatured, it was found necessary to remove some redundant skin, and the resulting scar was roughly Y shaped, the right arm and stem of the Y extending from the tragus of the ear to the symphysis menti below the mandible, in a natural crease of the neck. The left arm of the Y extended for about two inches transversely across the neck from the angle of the jaw. Recovery was uneventful. The wound healed rapidly leaving a healthy scar and patient was discharged on 22nd March, 1933, feeling very pleased with his improved appearance (figure 2).

Fig. 2.

The tumour weighed 4 pounds. A portion was sent to the Provincial Laboratory, Peshawar, for pathological examination, and was subsequently reported to be a fibro-adenoma.

I am indebted to Major D. V. O'Malley, O.B.E., I.M.S., Civil Surgeon, Mardan, who examined the patient and advised operation, and who gave me permission to publish the case.

A CASE WITH ABSENCE OF POLYMORPHONUCLEAR LEUCOCYTES

By S. P. GUPTA, B.Sc., M.B., B.S.

Demonstrator in Pathology, King George's Medical College, Lucknow

A. A., aged 26, Mahommedan male, was admitted to the King George's Hospital with the following complaints (1) pain in the abdomen, (2) masses in the abdomen and (3) occasional fever for four months. He gave a history of pain in the right testicle eleven years ago, and jaundice seven years ago. The first appearance of the abdominal tumour was preceded by severe pain in the left lumbar and hypochondriac regions. The patient felt the mass moving about in the abdomen and whenever it reached the hypogastric region he felt great discomfort and a sort of twisting pain. During attacks of fever of three or four days' duration the swelling of his abdomen used to enlarge.

The patient was anæmic but not emaciated. He had a coated tongue, clean teeth, and a thick and enlarged uvula. Definite, hard, lobulated, and movable masses were palpable in the right hypochondriac, umbilical and lumbar regions. Liver and spleen were not palpable. Inguinal, axillary, and cervical glands were not enlarged. Only a small gland was palpable in the left supra-clavicular region.

Though the possibility of Hodgkin's disease was never excluded the patient was kept on routine treatment for abdominal tuberculosis. He was afebrile for two weeks after admission, and his weight increased by one pound. In the first four days of the third week he had a temperature of about 101°F. and in the last three days it came down to normal. In the fourth week there was a similar rise of temperature. As the abdominal masses were enlarging, and becoming prominent, an exploratory laparotomy was suggested but it was not done on account of his low condition. In the fifth week the temperature again began to rise and reached 104°F. His pulse rose to 150 and respiration to 50 per minute. A blood count was done. Total leucocytes were 5,600 per c.mm., and a differential count showed lymphocytes 80 per cent, and large mononuclears 20 per cent. Polymorphonuclears were totally absent. Though the general outlook did not seem bad, the patient died the same day, and, unfortunately, no post-mortem could be held.

Comments.—Whatever the diagnosis may be, the point of greatest interest was the terminal blood picture. The absence of polymorphonuclear leucocytes has never before been noticed in this hospital. Such cases are rare in the literature too. Schultz first described this condition in 1922 under the term 'agranulocytosis'; and, as throat lesions were associated with it, Freidman suggested the title of 'agranulocytic angina', and as such cases without any throat lesions were described the term 'idiopathic neutropenia' was suggested. But, as some cases were definitely secondary, Schilling's 'malignant neutropenia' was considered to be the best name for this condition. For such a blood picture as was observed in our case 'absolute granulocytopenia' seems to be the most expressive. It is probably an end result of the action of some toxic agent, on the granulocytopoietic activity of the bone marrow.

As there were no throat lesions in the above case, it does not fall in the group of 'agranulocytic anginas'. His age, the chronic condition of the disease, and the absence of glands in the neck are against the diagnosis of glandular fever. Fever and matting of the abdominal tumours were certainly in favour of tuberculosis, but such large masses are rather rare in abdominal tuberculosis. On account of the chronic history and absence of myeloid changes in the blood picture, acute or chronic lymphadenitis or lymphatic leukaemia are excluded.

The most likely diagnosis is that of lymphadenoma, or as it has been lately called reticulo-endotheliosis. Jaffe has described a case.

of typical Hodgkin's disease with 800 white cells and 100 per cent lymphocytes. Our case is similar to that of Jaffe. The increase of monocytes to 20 per cent is more likely to be met with in cases of reticulo-endotheliosis than in tuberculosis. The absence of any myelocytes suggests that the absolute granulocytopenia was due to some toxic action and not due to a lymphadenomatous invasion and consequent metaplasia of bone marrow.

The other possibility is that of malignant endothelioma or Ewing's reticulum-cell sarcoma. But, as it has the histological characters of acute Hodgkin's disease this diagnosis is justifiable.

My thanks are due to Lieut.-Col. G. T. Burke, I.M.S., Physician to the King George's Hospital, for kindly allowing me to publish this case.

GONORRHOEA IN A BOY OF SEVEN

By A. R. MANSOOR, M.D., D.P.H.

University Hospital, Aligarh, United Provinces

THE occurrence of gonorrhoea in female children is fairly common, but the incidence of the disease in a boy is rare.

S. M., male, seven years old, was brought to me.

The history given was of burning during micturition, followed in a couple of days by the passage of a few drops of blood, and then a spurt of pus instead of the expected stream of urine.

On examination the meatus was found gummed up, and on separation a little thin purulent material was obtained on a platinum loop and a slide prepared.

The child's urine was clear and of a greenish tinge. I thought that probably he had infected himself with *B. pyocyaneus* by introducing something into the urethra.

However, on examining the slide pus cells and gonococci were seen in such abundance that there was no doubt of the diagnosis.

The method of infection was not ascertained but one of the male servants in the house was found suffering from acute gonorrhoea, so it is possible it was acquired accidentally from him.

[Note.—Abstracted by the Editor.]

A LEECH IN THE MALE URETHRA

By MON MOHAN GHOSH, L.B.Dr.

Medical Officer In-Charge, Kamalganj Dispensary, Sylhet

SOABULLA, aged 35 years, came to this dispensary on 10th November, 1932, and gave the following history:—

When washing jute in a pool of water he felt a pricking sensation in his penis. He came out of the water and was frightened to see that a big leech was entering his urinary canal. The leech entered the canal and disappeared as soon as he tried to pull it out. He came to the dispensary immediately and on palpation I felt a hard mass about one and a half inches in length in the urethra. The mass began to increase and the patient became very restless, he tried to urinate but could not pass any urine.

I first tried to pass a probe into the urethra but was unsuccessful. On the second attempt to seize the leech with a pair of sinus forceps I was successful and extracted it. Bleeding from the meatus continued for

some hours but by next morning it had entirely ceased and the patient had no further trouble.

I wish to thank Lieut.-Col. J. L. Sen, M.C., I.M.S., for his interest in the case.

ABILITY TO WALK A LONG DISTANCE AND GIVE DYING DECLARATION AFTER SEVERE HEAD INJURY*

By RUDR DUTT, L.M.S.

Assistant Surgeon, Dera Ghazi Khan

A HINDU adult male, after receiving severe head injuries, proceeded from one place to another in search of assistance, but failing to find any he finally went to the local police station and made a report as to how the injuries were received. The search entailed a walk of well over two miles.

The following injuries were found after death:—

On the right side of the head there was a large contusion covered with blood clot in the temporal region with a smaller one behind the ear. The right eye was displaced by a large orbital haematoma. He also had a contusion over the left parietal region.

There was a comminuted fracture of the right parietal bone, and a fracture of the base of the skull extending into the middle fossa, with rupture of the right middle meningeal artery and a large extra-dural blood clot. There was also a small contusion in the frontal area of the brain.

This case is reported on account of its importance from a medico-legal point of view.

PASSAGE OF A NEEDLE THROUGH THE ALIMENTARY CANAL

By V. KRISHNA MENON, L.M.P.

City Clinic, Chalapuram, Calicut

AT about six o'clock in the evening, 24th April, 1933, a girl, 12 years of age, was brought by her father, with a history of having accidentally swallowed an unthreaded sewing needle half an hour before. She had been made by her grandmother to swallow immediately a wad of cotton-wool.

After the throat was examined, she was made to swallow a piece of bread, which did not elicit any pain or irritation. Next she was given a full and heavy meal consisting of bread and plantains only, and kept under observation. Only solids were enjoined for the first twenty-four hours and a strict watch was kept on all motions passed thereafter.

From the 25th evening, she was allowed thick curds and on the following day a little milk also. One ounce of liquid paraffin was given in the forenoon of the 27th. Previously the girl had one motion on the night of the 24th, and three on each of the next two days. The second motion after the paraffin was washed through a sieve, and the needle was found blackened and with some encrustation—about seventy-two hours from the time of swallowing. It was an ordinary sewing needle about four centimetres in length.

Passage of a needle through the whole length of the alimentary canal must be a very rare occurrence hence this case has been reported.

OCTOBER

THE PROBLEM OF LEPROSY

It is generally believed that leprosy is an infectious and contagious disease. This is of course the old traditional belief practically all over the world, and for many centuries there were in most countries laws and customs which aimed at preventing contact between healthy people and lepers. The medieval laws concerning lepers in Europe have often been quoted.

In the nineteenth century however the work of Danielsen and his followers challenged the belief in the infectiousness of leprosy and the result was a slackening of attempts at segregation of lepers in some countries. Towards the end of the nineteenth century when Hansen discovered the bacillus, the pendulum swung back again and while Jonathan Hutchinson's 'fish theory' caused a temporary diversion, the belief in the infectiousness of leprosy once more became general and there was a correspondingly increased effort to segregate lepers.

The country concerning which we have most accurate data is Norway, and the history of leprosy there may be summarized as follows:—

The disease was present in the middle ages; there was a leper hospital at Bergen in 1266, and others were established later elsewhere. By the end of the 16th century leprosy was reported as much diminished and most of the leper hospitals were closed; nevertheless the disease still exists. In 1839 there were 287 lepers in institutions and general interest in the reported increase of leprosy at that time brought about the appointment of a Royal Commission as the result of which more leper asylums were opened and 2,858 cases of leprosy were detected. In 1857 laws were passed to enforce segregation of cases in institutions or in the patients' homes. From that time there has been a steady decrease of leprosy in Norway, the official figures being in 1856 2,858, in 1875 1,752, in 1890 960, in 1900 577, in 1910 326, in 1920 160, and in 1930 69. Most of the cases now remaining are of very long standing and, during the five years 1926 to 1930, only three new cases were detected.

These facts appear to be conclusive proof of the efficacy of segregation, but there are two objections which may be made. The first is that this reduction is due very largely to improved social and hygienic conditions in Norway, and would probably have occurred without any segregation. The second is that, while such measures may be practicable in countries such as Norway with a comparatively small number

of lepers, with its considerable resources and with its educated population, they are impracticable in other countries where the number of lepers is much larger, the resources are less, and public opinion is uneducated. The first objection is difficult to refute and the second is undoubtedly true in some countries.

Nevertheless in some oriental countries, compulsory segregation has been tried, but the efficacy of the measure has not yet been conclusively demonstrated, and is still largely a matter of opinion. An interesting example is that of the Philippine Islands. In 1906 an island leper colony was founded and all detected lepers were induced, or if necessary compelled, to go there. This measure was hailed by some as being the death-knell of leprosy in the Philippines. The experiment has now been in progress for twenty-seven years and many practical difficulties have been encountered. There was much concealment of the disease, and this difficulty was possibly aggravated by harsh measures but, during recent years, a wiser handling of the patients has greatly helped in inducing them to undergo voluntary segregation. Also the institution of treatment, with the subsequent discharge of many patients on parole, has created a better feeling. Nevertheless it cannot yet be said that leprosy has been much reduced in the Philippines. What is lacking is the support of the segregation laws by enlightened public opinion. This is the great difficulty of all leprosy work in countries where education is comparatively undeveloped.

The problem of leprosy has been influenced by two developments which have taken place during the last few decades.

The first of these, the improvement in treatment, has attracted most attention. Treatment by injection of chaulmoogra and allied oils and their derivatives was started about 1890 and promising but not striking results were claimed by various workers; but later, technical improvements were made and from 1915 onwards far better results were claimed. Unfortunately, hopes too often were regarded as proved facts; improvement in the visible lesions was too often interpreted as indicating a cure. Stamping out leprosy by treatment soon came to be regarded by some as a possibility but there were many sceptics. Later, careful observers found that the results of treatment did not justify some of the claims that had been made. Others, failing to obtain striking results, went to the other extreme in their reaction against excessive optimism and stated that treatment was useless. This we consider to be a mistake. Treatment is far from being completely satisfactory, but under favourable circumstances in suitable cases it does produce improvement which is often permanent.

The other development, which has attracted less attention, but which may ultimately prove

to be more important than advances in treatment, has been in the greatly improved knowledge of the slighter forms of leprosy. In this development Indian workers can claim the greatest share. Many slight lesions in the skin, such as depigmented macules with slight anaesthesia, are now known to be due to leprosy although bacteriological examination is negative. We have found that this knowledge, which until recently was not common among medical men, was quite common among Indian villagers in some places. We have found that Indian villagers can sometimes diagnose leprosy at a stage when most doctors would fail to recognize it. Patients with one or a few such macules are very common in India and we know that many of these lesions undergo spontaneous arrest. Such cases are reported as being much less common in other countries. It is an open question whether this really is so, or whether they are present and are not being diagnosed. This certainly was formerly the case in India. It is now becoming generally recognized also that in endemic areas many people must become infected but never show any signs of the disease, and in fact those who develop the disease are probably only a fraction of the total number infected.

These two developments, the increase in our knowledge of the onset of leprosy, and the improvements in treatment, have markedly affected anti-leprosy work. The diagnosis of slight cases has led to a marked increase in the number of people reported as suffering from leprosy. The 1931 census reports an increase over the 1921 census of 44.2 per cent in the number of cases in India, and in some areas where leprosy propaganda work has been done the increase is over 100 per cent. These increases are probably more apparent than real, and are due to more accurate enumeration, although leprosy may be increasing in some areas, and it is probable that in India there are between one half and one million people showing definite signs of the disease.

Earlier diagnosis has also revealed the fact that only about one-third of the cases with definite signs of leprosy are discharging bacilli and are therefore considered infectious.

The development of treatment, although not doing all that was hoped and even claimed, has made a great difference to anti-leprosy work in India. The doctor and the health worker used to regard cases of leprosy as highly infectious and incurable, and hence the patient had no inducement to go to them for relief; but now we have treatment to offer, not a rapidly effective treatment it is true, but effective enough to bring patients in large numbers to doctors.

From the above outline it is obvious that the leprosy question has been in the melting-pot during the last decade. Various workers in many countries have expressed widely differing

views regarding the control of leprosy by segregation and by treatment. A leprosy commission of the Health Organization of the League of Nations was appointed to try to clear up some of the confusion. The first general session of the commission met in Bangkok in 1930 and was attended by authorities on anti-leprosy work from various countries. The report of this commission is a valuable document which discusses the principles of the prophylaxis of leprosy chiefly from an administrative standpoint. The Leonard Wood Memorial Conference on leprosy met shortly afterwards in Manila and the report of this deals with leprosy in its more technical aspects. This conference led to the formation of the International Leprosy Association and to the publication of the *International Journal of Leprosy*, the first number of which has recently reached us.

An attempt is now being made to apply in India the principles advocated by the Leprosy Commission of the League of Nations in their report, and, to consider this matter, a conference of leprosy workers from various parts of India was convened in Calcutta in March 1933, by the Chairman of the Indian Council of British Empire Leprosy Relief Association (Major-General Graham, O.B.E., C.I.E., I.M.S.). The resolutions and recommendations of this conference are published in this number of the *Gazette*.

There are two big organizations engaged in anti-leprosy work in India. The oldest is the Mission to Lepers which owns or aids no less than fifty-two leprosy institutions with accommodation for 8,400 patients. These institutions act as centres of segregation and treatment and to some of them are attached out-patient clinics which large numbers of patients attend; and some of them act as centres of training of doctors and others in anti-leprosy work.

The other organization is the Indian Council of the British Empire Leprosy Relief Association. This is a semi-official organization with branches in all the provinces. Its aims are to further research in leprosy, to survey the incidence of leprosy in India and to organize treatment and preventive work through out-patient centres.

There are in addition some institutions run by Provincial Governments, and work in out-patient centres organized by local authorities, by industrial concerns, and by private bodies. It is highly desirable that in India there should be a general policy of anti-leprosy work, in which all these various agencies may have their share. This policy the Calcutta conference has tried to formulate, not in great detail but in principle. The principles advocated by the conference should command general acceptance.

Anti-leprosy work should not be separated but should be an integral part of the general public health and medical work of the country. Leprosy cannot be controlled by treatment alone

nor by segregation alone, but a wise combination of these two measures may effect much more than either measure separately. Treatment brings the patients under observation, wins the confidence of the people and thus provides the opportunity for propaganda with a view to prevention. This propaganda helps to spread a knowledge of leprosy, which brings more patients for diagnosis and treatment. Leprosy clinics; in-patient institutions, leprosy hospitals and asylums all have their place, an important one in anti-leprosy work, but there is a need for co-operation and co-ordination of the work of different agencies. While many patients are not considered infectious and do not therefore need isolation, many are infectious, and the isolation of the latter is undoubtedly the most important step to be taken whereby to control leprosy. Isolation of all infectious persons in institutions is impossible but accommodation should be available for all those willing to undergo voluntary isolation. The institutions of the Mission to Lepers perform an important service in providing such accommodation but it is not nearly adequate to meet the needs, and more such institutions are undoubtedly needed. Many patients are not willing to submit to voluntary isolation and the only available method of procuring their segregation is, by teaching, so to educate public opinion that isolation in their homes and villages is insisted upon by the villagers themselves.

The resolutions of the Calcutta conference advocate the setting up of non-official leprosy boards in endemic areas, in order to arrange

for co-operation between the different bodies engaged in anti-leprosy work. They advocate the more thorough organization of training of doctors and health workers, and the establishment in endemic areas of special leprosy clinics to act as centres of treatment, of preventive work and of training for medical men. In addition leprosy clinics in general hospitals should be encouraged.

The need of increased accommodation in in-patient institutions for infectious cases of leprosy is emphasized. The need of further research is recognized, and the organization of epidemiological research in a rural centre is advocated. The importance of examination of school children and labourers in industry for signs of leprosy is stressed. The recommendations of the conference also cover such subjects as the importance of general treatment, the most effective forms of special treatment, the need for observation and after-care of quiescent and arrested cases, the employment of non-infectious patients, and the question of non-infectious cases in school children.

The conference has already borne fruit in that the Surgeon-General of the Madras Presidency has called together a leprosy conference of medical and social workers at which the findings of the Calcutta conference were considered and arrangements were made for putting many of its resolutions into effect.

This Calcutta conference should be a landmark in the history of leprosy in India and will we hope help greatly in the development of anti-leprosy work along sound lines.

Special Article

THE EARLY SIGNS OF MENTAL DISORDERS

By OWEN BERKELEY-HILL

LIEUTENANT-COLONEL, I.M.S.

Medical Superintendent, Ranchi European Mental Hospital

INSTRUCTION in the early signs of mental disorder does not receive anything like the attention it deserves in medical schools and colleges in this country. Teachers of psychiatry still devote far too much time to expositions of full-blown psychoses. A glance at the majority of the syllabuses on psychological medicine or at the type of questions set in examination papers will corroborate this statement. No doubt instruction in the psychoses is not wholly without interest but for the majority of medical students the interest is more theoretical than practical because only a small percentage of medical students has any intention of becoming alienists. What the general practitioner, not

to mention the specialist in medicine, surgery and gynaecology, wants or should want to know, is the early signs of mental disorder in their own patients. Frequently practitioners of medicine, surgery, gynaecology and so forth are so ignorant of what constitutes mental disorder that they fail to recognize it when it is staring them in the face.

Before we proceed to consider the early signs of mental disease, it will be not without advantage to pause for an instant to try and formulate some idea as to what constitutes mental disorder of any kind whatsoever. The world is becoming daily fuller and fuller of books dealing with mental phenomena of every conceivable variety but how few appear to take into consideration the enormous complexity of the problems with which they deal, but carry on in such a light-hearted fashion that even the least sceptically-minded of us may well wonder what on earth it is all about. To give a satisfactory definition of any disease is no easy

matter. Indeed, a definition of what constitutes 'disease' is generally omitted in textbooks of medicine and surgery. The omission is ominous. The same observation holds good for textbooks on mental disease but here there is some excuse for the omission because to establish the existence of mental disease we have no other standard to go upon than social convenience. This is highly arbitrary, hardly less so than our judicial code. People consult mental specialists when they are either intolerable to themselves or to other people. In the latter case some form of coercion is generally necessary to bring the consultation about.

Let us suppose that a change takes place in our social conditions, whereby a type of mental disorder which is now regarded as intolerable becomes innocuous or even advantageous. What will happen then? It is one thing to say that we will get rid of one kind of mentality because, under existing conditions, it is unendurably tiresome, and quite another to say that this or that type of mind is in itself wholesome or unwholesome. Primitive types of mind are regarded as insane whenever they appear in a so-called civilized society. On the other hand, it seems quite likely that the average citizen of London to-day would have been counted at least mentally defective had he appeared in ancient Athens. In the same way, if a man of the future has ever been born into this twentieth century of ours, he may very well be in an asylum or a jail now.

One of our main difficulties is that we only know very roughly and uncertainly what we do not want of the human mind. As to what we ought to want—will such knowledge ever be possible? Would it, we may ask, have been safe to have allowed a mental specialist to pass an opinion on the mental condition of many great men of the past—John Bunyan, Jonathan Swift, William Blake, Thomas De Quincey, Samuel Coleridge, Percy Bysshe Shelley and Edward Thomas, to take a few examples from eminent men of letters? Our modern psychotherapists might very well have cured Bunyan of his terrible anxiety states about religion, and Shelley of his atheism. The fierce bitterness of Swift might to-day be analysed away and 'treatment' of various sorts might have made it unnecessary for De Quincey and Coleridge to remain morphia addicts and Thomas to renounce alcohol. A course of occupational therapy might have stopped for good those wonderful visions of Blake. But had these 'treatments' been carried out with what psychotherapists nowadays would deem success, what would have been the effect on English literature? Would it have been deprived of 'Pilgrim's Progress', the 'Tale of a Tub', 'Songs of Innocence', the 'Confessions of an Opium Eater', the 'Ancient Mariner', 'Adonais' and 'Like the Touch of Rain'? It seems not improbable. As the author of 'Sisyphus', that amusing

satire on psychology and its exponents, observes: 'It is chastening to reflect that the persons we most admire in past ages were often those who were, in their own day, the least at home in the world'.

The founder of Christianity was so little adapted to the age in which he lived, that he got himself executed as a common criminal. Yet Christianity could never have existed had he not been executed. On the other hand, as Jung has pointed out, an individual well adjusted to a mistaken society may perish with it. If it were adaptability rather than adaptedness that were in question, the ideal would be more understandable. But when all has been said on this point it is in a limited sense to every one's interest that they should be as well adapted as possible to their particular position in life.

On this assumption we may now pass on to consider the theme with which this paper is primarily concerned, namely, the early signs of mental disorder. First, and by far the most important as a sign of mental disorder, is a permanent change in the behaviour, because a change in behaviour means a change in temperament and character. But not all permanent changes in behaviour connote insanity. A Christian who becomes a Mahomedan, or a Mahomedan who turns Christian is not necessarily exhibiting signs of a disordered mind by so doing. St. Augustine, the greatest of the Latin Fathers of the Church and one of the foremost scholars of his age, could hardly be held to have been mentally disordered when he embraced Christianity and was baptized at the age of 33, when up to then he had led what is commonly termed an immoral life and had been a prominent member of the sect of Manichæans who worshipped the devil. No, the change in behaviour which generally connotes some mental disorder is generally a change for the worse, not for the better. A quiet, placid, kindly nature becomes, with the onset of insanity, moody, taciturn, sullen, quarrelsome or even cruel. A truthful individual whose mind is diseased may take to lying and a modest person may turn into a boaster and braggart. A clean, tidy, well-groomed man may become dirty, with the onset of insanity. He ceases to pare his nails or to have his hair cut as heretofore. He omits to shave or bathe himself properly. He may neglect his family as well as himself. Sooner or later he neglects his business. He may take to alcohol or drugs of some sort. A sociable man may suddenly become shy to the extent of avoiding the company of others and keeping as much as possible to himself. Mental disorder may be ushered in by loss of sleep or loss of appetite, or both. A thrifty man may suddenly become extravagant. While hitherto accustomed to order a single suit of clothes at a time, he now places an order for a dozen suits.

Hitherto accustomed to go to his office on a bicycle or in a public conveyance, he takes suddenly to taxis or even buys a car of his own. A devout man, hitherto regular in the practice of his religion, suddenly ceases to pray or read the Scriptures. He may go so far as to brag openly that he believes in nothing, that all religion is nonsense and that what the world wants most is colleges for the instruction of young men and women in atheism. A devoted husband may desert his wife or introduce a strange woman into his house as his mistress. A kind and loving father takes to ill-treating his children, calling them brats and turning them into the street. Last of all, the mental disorder may lead to the commission of a crime of some sort, and that generally one of violence.

Most doctors are aware nowadays of the marked deterioration, frequently of very sudden onset, that occurs in children who have suffered from encephalitis lethargica (sleepy sickness). Well-behaved, truthful and industrious children become troublesome, lazy and boisterous and frequently take to lying. Such children very often come into collision with the law as they often commit offences, particularly that of stealing. In short, a doctor, who sees a man or a woman or a child, with whose temperament he is well acquainted, beginning to exhibit traits of character other than those he has observed hitherto, should suspect the presence of some form or other of mental disorder. In the case of a child, a doctor would only be doing his duty in bringing the matter to the notice of the child's parents. In the case of an adult the matter is more delicate, because the great majority of people still regard mental disorder

in the same light as cancer and venereal disease were regarded fifty years ago, that is, as something too dreadful to talk about. Hence it is sometimes by no means easy to tell a man or woman that he or she is showing symptoms of insanity. Good intentions of this description often meet with violent opposition. However, where there is a will there is often a way, so that a doctor, who appreciates fully the importance of early treatment in mental disorder, should be able, somehow or other, to persuade the afflicted person to consult a specialist. If this is in no way possible, it is the doctor's duty to bring the state of affairs to the notice of some near relative and recommend that appropriate measures be taken without delay.

In matters of this sort it is evident that a doctor, who is not a trained mental specialist, must depend more on intuition than on knowledge. Indeed, in almost any branch of medicine the most successful practitioners seem to be those who realize that to understand human nature it is not enough to study what scientists can tell us. 'The possible twists in the maze of consciousness', says the author of 'Sisyphus', 'are endless and no psychologist is ever likely to find his way through them, however many trials and errors he may make'. A psychologist may try to escape consciousness, as does the founder of the Behaviourist school of psychology, by denying its existence, but few have the courage or the blindness for that counsel of despair. As the author of 'Sisyphus' says, 'it is only the artist, edging towards the mystery, darting from tree to tree, catching glimpses instantly lost again, who can begin to show us something of our own uniqueness'.

WORKMEN'S COMPENSATION IN INDIA NEW PROVISIONS

WE have received from the Calcutta Claims Bureau a copy of a pamphlet, recently issued, containing a summary of the important proposed amendments to the act contained in the new Workmen's Compensation Amendment Bill, as finally amended and approved of by the select committee of the Legislative Assembly. Alongside each proposed amendment is shown the existing provision, if any, under the act so that employers of labour and other persons interested in workmen's compensation matters may see at a glance the changes likely to be made as compared with the existing legislation, when the new bill is finally passed into law.

The pamphlet explains the many radical changes which are foreshadowed in this important piece of legislation and it also contains two comparative tables showing the benefits under the existing act and the benefits now proposed under the bill for each of the wages classes. A comprehensive list of persons who will be deemed to be 'workmen' under the new legislation has been included.

Workmen's compensation is a subject which concerns practically every large employer of labour and many new classes of employees, to whom the act has not

hitherto been applied, will now shortly be brought within the scope of the legislation.

We recommend that every employer should acquaint himself with these provisions by obtaining a copy of this pamphlet either direct from the Calcutta Claims Bureau, 26, Dalhousie Square, Calcutta, at a cost of annas eight per copy, or from any of the leading insurance companies.

THE CEYLON SANITARY INSPECTOR

WE have received a copy of the first issue of a new journal *The Ceylon Sanitary Inspector*. This number is really a report of the proceedings of the first conference of District Sanitary Inspectors, which includes several papers on matters of interest. No doubt this journal will be of use to the sanitary inspectors of Ceylon as it will provide a medium whereby they may discuss their problems. There is no mention of how often it is proposed to publish this paper, what is its price, where it may be obtained nor who publishes it. If it is hoped to obtain a circulation outside the circle of the Ceylon sanitary inspectors themselves we would suggest supplying the above information on the cover of the next issue.

FIFTY YEARS AGO

(From the *Indian Medical Gazette* of October, 1883, Vol. XVIII, pp. 265, 271, 272 and 283)

CAN CHOLERA BE GENERATED *DE NOVO*?

By SURGEON-GENERAL S. C. TOWNSEND, C.B.

In my paper on the 'Variations in the incidence of cholera', which you were good enough to publish in the numbers for March and April, after adducing evidence that the degree of incidence on a unit of population was determined by the condition of its water-supply, I pointed out that even if this were conceded there would still remain, for further enquiry, the nature of the relation between impure water and the primary or essential cause of cholera, and that one of the questions to be decided was whether cholera could be generated in water *de novo*. I have always held it possible that cholera might be so generated under favourable atmospheric conditions, but in the very large number of outbreaks which I have investigated in the course of the last ten or fifteen years, the instances in which importation of infective material by human intercourse was not a more probable immediate cause of the outbreak have been very rare. An outbreak, however, of a disease which at all events closely resembled cholera recently occurred in the Lahore district, under circumstances which afford no ground for suspecting importation, and as it has on this account an important bearing on the above question, I trust you will favour me by giving a place in the *Gazette* to the following report, and also to the descriptions of two outbreaks which were severally the first appearances in wide tracts of country of the great epidemics of 1868-1869 and of 1875-1876 in Central and Western India.

The history of these three outbreaks illustrates the difficulty of solving the question whether cholera is ever generated *de novo*. In the first instance there was no ground for suspecting importation, but there is want of certainty that the disease was true cholera. In the other two instances probability of importation, though slight, cannot be altogether excluded, but inasmuch as they were isolated outbreaks, or first outbreaks after long intervals of freedom from epidemic prevalence, the probability is great that the conditions under which they occurred are those under which cholera is generated if it ever is generated *de novo*. The conditions present in all the three outbreaks above described were intense heat and great dryness of atmosphere, and water used

for drinking in which organic impurities were highly concentrated; in the two outbreaks last cited, the death of the fish and their subsequent putrefaction probably gave greater intensity to the views.

August, 1883.

ON ENTERIC FEVER

By SURGEON W. E. SAUNDERS, A.M.D.

MUCH enteric fever is classed under that great cloak for our ignorance, the term simple continued fever; but it would be far better if we had the courage of our opinions and called all suspicious cases of fever, lasting over two days, by their correct name; lest, by neglecting to do so, we tempt the attendants to be careless as to the disposal and disinfection of the stools, and so give rise perhaps to fresh cases and a spread of the disease. We must act on our own experience, or we may be led astray; for instance the majority of our leading physicians consider milk the best diet in fevers, especially if the bowels are affected, but Hippocrates did not allow milk to be used particularly in the latter cases. We must be careful, therefore, to place no blind adherence to the old masters or fathers of medicine, but act as our own experience leads us to consider best.

To a great extent successful physicians hold a despotic sway over their professional brethren, and a doctrine introduced by an outsider as it were in the investigation of a disease, one phase of which only is common in England, finds that, after years of research, the doctrine evolved obtains little hearing, and the truth in fact runs the risk of being almost crushed by the authority of a few great names, as happened with the ipecacuan treatment of tropical dysentery.

If all Army Medical Officers were to record their experience in enteric fever (for, being extended as it is to all parts of the world, it must be unequalled) they could add much to the knowledge of this disease. Difficult as it is, owing to frequent moves, to give our experiences to the professional world in anything approaching a complete form, still we might all of us by recording facts, and not merely our deductions and impressions, convince our professional brethren, who are not so fortunate as to have seen this disease in all parts of the globe, that there is yet much to be learnt regarding the ætiology at least of enteric fever.

We estimate our knowledge of disease too highly, and though few are willing to own it, medical science is really still in its infancy.

Current Topics

Treatment of Menstrual Irregularities

By WILFRED SHAW, M.D., F.R.C.S., F.C.O.G.

(Abstracted from the *British Medical Journal*, 27th May, 1933, p. 907)

THE type of patient now under consideration is the woman who has some form of menstrual irregularity independent of the presence of either tumour or inflammation of the pelvic organs.

EPIMENORRHOEA

In this form of menstrual irregularity the patients menstruate with a cycle less than the normal twenty-eight days—usually with one of twenty-one days or with one of fourteen. Typically the menstrual cycle is constant, and is not irregular. In some cases, in addition to a reduction in the menstrual cycle, the duration of the hæmorrhage is prolonged and the amount lost on each day is increased. This clinical form of menstrual irregularity is very common, but it must be emphasized that epimenorrhœa in itself is not a disease but merely

a symptom. Cases of epimenorrhœa can be classified into fairly well-defined groups. The post-partum type is seen very often indeed, and when such patients start menstruating after parturition the cycle is reduced from one of twenty-eight days to one of twenty-one or fourteen. Post-partum epimenorrhœa may, of course, complicate inflammation of the Fallopian tubes and ovaries, but such cases are relatively few, and in the common form no lesion can be detected in the pelvis. As I have already stated, these cases are probably related to a disturbance of the endocrine balance, and are perhaps due to over-activity of the anterior lobe of the pituitary.

Epimenorrhœa occurs most frequently, however, in patients about the age of 45, when they are approaching the menopause. It is almost invariable that the amount of blood lost at each period is excessive, and quite often leads to a severe degree of anæmia. Not seldom the uterus is found to be enlarged, and is harder than normal. Until recently such cases were grouped under the term 'chronic metritis', but since the advance in

our knowledge in the physiology of menstruation it has become generally recognized that both the epimenorrhœa and the uterine hypertrophy are due to over-activity of the ovaries. Epimenorrhœa is also common in cases of fibroids, particularly in patients over the age of 40. In another group it develops in patients about the age of 35, most of whom are single. Sometimes it is associated with salpingo-oöphoritis, and sometimes with chocolate cysts of the ovary. The ætiology of these cases of epimenorrhœa is not known with certainty. At the present day it is generally accepted that it is not related either to an inflammation of the appendages or to any local lesion in the uterus itself. Almost certainly the condition is due to an abnormality of ovarian function, although there is no proof that the primary fault lies in the ovary; it may very well be that the pituitary is primarily responsible.

Treatment

The treatment of epimenorrhœa is one of the most difficult problems in gynecology. One has to deal, not with a diminution of activity for which an appropriate hormone might reasonably be administered, but with over-activity, and the question is essentially one of inhibition of ovarian activity. Now, it is quite clear that whatever pharmacological properties may be claimed for the various ovarian and pituitary hormones, no one has at any time suggested that any one of these has an inhibitory effect on the ovary. For these reasons one is very sceptical as to whether the administration of any ductless gland preparation is likely to be of benefit in a case of epimenorrhœa. These theoretical considerations are borne out by my own experience, and I have personally given both œstrin and the anterior pituitary hormones to cases of this kind without result. When we turn to the prescription of drugs in the treatment of epimenorrhœa it is clear at the outset that there can be small hope of success. The only way in which such drugs could act is by inhibiting ovarian activity. It is true that the amount of blood lost during each period can be controlled by drugs such as ergot and by proprietary preparations such as femergin, but it is difficult to conceive that there is any drug on the market which possesses the remarkable property of inducing a specific inhibitory effect on the ovary. Again these theoretical considerations are borne out by clinical experience. The question now arises as to what can be done for these cases. In patients of 45 or over treatment as a general rule resolves itself into the creation of an artificial menopause. The patient is anesthetized, the uterus is curetted, and then a tube containing 50 mg. of radium is inserted into the uterus and kept there for forty-eight hours. This is an excellent remedy so far as the uterine bleeding is concerned. It is true that the results are often not immediate, and patients occasionally have one or two periods after the application of radium; but it is very exceptional for further bleeding to take place. Sometimes the first hæmorrhage after radium is copious, because the radium itself produces a local inflammation in the endometrium, and this hyperæmic area bleeds excessively during the menstrual period. There are two other objections to radium treatment: one is that almost invariably there is a persistent vaginal discharge due to the local inflammation of the endometrium, and the second is the onset of menopausal symptoms. After the age of 45 severe menopausal symptoms as the result of the creation of an artificial menopause by radiological means are not usual, although they are extremely common under the age of 40 and fairly common between the ages of 40 and 45. It is difficult to give an opinion as to whether the patient is likely to develop these menopausal symptoms if an artificial menopause is brought about; and if the patient is a good subject for an operation, with a thin abdominal wall, I often prefer hysterectomy with conservation of the ovaries to radiological treatment. It should be emphasized that with modern technique hysterectomy has a very low mortality, and if a patient survives the operation and has her ovaries retained she

is much more likely to be free of symptoms than if an artificial menopause is induced radiologically. So far as x-ray treatment is concerned, the end-results are similar to those obtained after the application of radium. The great drawback to x-rays, however, is that for sound therapy the uterus should be curetted prior to treatment, so that carcinoma of the body of the uterus or of the isthmus can be excluded.

Whereas the treatment of epimenorrhœa in patients approximating to menopausal age is fairly successful, that in younger patients is extremely difficult. Both x-rays and radium are, in my view, contraindicated as a means of producing a permanent artificial menopause, which in patients younger than 40 almost invariably leads to appallingly severe menopausal symptoms; and one of the worst sequels is the development of kraurosis vulvæ, with its attendant symptoms of pain and dyspareunia. Cases of this sort are sometimes encountered, and it is not an exaggeration to say that the resultant symptoms often produce more distress than the original epimenorrhœa. Theoretically the induction of a temporary artificial menopause with either x-rays or radium would seem a satisfactory procedure, but in practice this is not so. The essential difficulty is to obtain the correct dosage, for if a small dose is given no effect is obtained, while if it is too large the result is a permanent artificial menopause. The margin is small, and experience at St. Bartholomew's Hospital has shown that it is extremely difficult to gauge with any accuracy the correct dosage for a temporary artificial menopause. My own view is that with x-rays so many factors—such as the location of the ovaries and the thickness of the abdominal wall—have to be considered that this form of treatment is unlikely ever to be used extensively: similarly with radium. I believe that the effect of radium is upon the ovary and not upon the uterus; and, again, it is difficult to gauge the exact distance of the ovaries from the radium placed within the cavity of the uterus.

The treatment of epimenorrhœa in patients prior to the age of 40 resolves itself into either expectant treatment or operation. In cases of post-partum epimenorrhœa experience shows that almost invariably the menstrual functions right themselves spontaneously in due course. Indeed, it is very rare to see patients who give a history of epimenorrhœa which has persisted for more than three years following childbirth. In these cases, provided the patient does not acquire a severe degree of anemia, the administration of such drugs as ergot during the menstrual period, combined with rest, is the wisest course to follow, and the return of the normal menstrual cycle should be awaited. In the other cases of epimenorrhœa the position is difficult. In those in which it arises without obvious cause in single women of the age of 35, clinical experience shows that it is exceptional for them to return to the old cycle of twenty-eight days. Whether operation is performed depends solely on the degree of anemia. If operation is decided upon the correct procedure is to perform subtotal hysterectomy and to leave the ovaries behind. It is quite clear that this method is drastic, and it is warranted only if the patients suffer from a high degree of anemia. The results of hysterectomy are extremely good: the primary mortality is low and the end-results are eminently satisfactory.

METROPATHIA HÆMORRHAGICA

The recognition of this disease is the outcome of researches on the menstrual cycle. The full description of the pathological conditions is due to Schroeder as a result of his investigations carried out at Rostock during the war. The disease is characterized by a complete upset of the menstrual functions, so that ovulation is inhibited and corpora lutea are not produced in the ovaries. Always a cyst is found in the ovaries, and has the structure of a cystic ripening follicle. The condition of the endometrium is that of a diffuse polypoidal hyperplasia, and large plum-coloured polypi project from the endometrium downwards towards the cervical

canal. The endometrium shows the changes of a true hyperplasia combined with cystic dilatation of the glands, and in the superficial layer large areas of necrosis can be observed. Premenstrual hypertrophy never develops in the endometrium because a corpus luteum is not found in the ovaries. Metropathia hæmorrhagica is not uncommon, and can be diagnosed with a fair degree of precision if due care is taken. It occurs most frequently about the age of the menopause, but it is also seen in young girls before the age of 20, and it is not unusual before the age of 30. The symptoms are fairly characteristic. Usually the patients give a history of a short period of amenorrhœa; this lasts for about six to ten weeks and is followed by continuous bleeding, which may persist for many months. (I have seen cases in young girls in which it has gone on for years.) The amount of blood lost on each day is not excessive, and it is rare for large clots or severe bleeding to be seen at any stage of the disease. The characteristic symptom is continuous bleeding, similar to the hæmorrhage of a normal menstrual period.

The treatment of metropathia hæmorrhagica corresponds almost exactly with that of cases of epimenorrhœa, with the exception that in the former we have to deal sometimes with young patients—patients below the age of 25. In these cases the first procedure to be employed is curetting. The whole of the endometrium should be carefully scraped away and the material removed examined microscopically so that the diagnosis can be confirmed. The results of curetting are not very satisfactory, and in most cases the continuous bleeding recurs within a few months; nevertheless, it is sometimes stopped and the normal menstrual cycle returns. There is, however, a tendency, even in these cases, for the disease to recur, and it is very interesting to notice that a cyst may form in the opposite ovary. In young patients with metropathia hæmorrhagica, if curetting fails the next line of treatment is to give anterior pituitary hormone either in the form of the prolan preparations or of Parke Davis's 'antuitrin S'. This method has been employed extensively in America and in Canada, and encouraging results have been reported; in my hands, however, they have not been good. Theoretically, this therapy follows the correct line, for the object of the administration of the anterior pituitary hormone is to stimulate the ovaries to produce corpora lutea. It may be that when more potent preparations are available this form of treatment will be generally adopted. In a few cases I have tried the application of small doses of radium of the order of 40 or 50 mg. for periods varying from twelve to twenty-four hours, but again I have not had any satisfactory results. This, again, is theoretically sound, for it aims at creating a temporary artificial menopause, but, as in all such cases, the essential difficulty is to give the correct dosage.

It might be thought that removal of the ovary which contains the cyst would lead to cessation of the symptoms. A fair amount of evidence has accumulated to show that the opposite ovary invariably becomes cystic within a short space of time, and the continuous bleeding recurs. Unfortunately, in young patients, if there is no response to the various treatments I have indicated, one is sometimes forced to perform hysterectomy and to leave the ovaries behind. It is obvious that such a procedure is very drastic and not to be lightly undertaken. In my experience the patient and her relations eventually insist upon the removal of the uterus, for it is not uncommon for a severe degree of anæmia to be produced by the continuous bleeding; the patient and her friends become tired of the unsatisfactory results of the methods employed, and she becomes insistent upon having the uterus removed.

HYPOMENORRHEA

In this type of menstrual irregularity the menstrual cycle is prolonged. The usual history given is that the patient menstruates every six weeks, and then perhaps every three months; she may then have a period of

amenorrhœa lasting for six months or even longer. Irregularity of the cycle, in which there is a wide interval between the menstrual periods, is a characteristic of hypomenorrhœa. It is seen most commonly in patients about the age of 30. So far as the menstrual functions are concerned, the cause of hypomenorrhœa is an irregularity of ovarian function, and histological investigations prove that ovulation and corpus luteum formation occur spasmodically. Two types can be distinguished: one in which the fault is primarily ovarian, and the other in which the fault lies in one of the other ductless glands, usually the pituitary; the ovaries are deficient secondarily. Patients with primary ovarian deficiency give a history of a late onset of puberty and irregular menstruation from the beginning; such patients frequently have spasmodic dysmenorrhœa, and not seldom are sterile. In addition, there are certain physical signs of primary ovarian deficiency, such as an ill-developed uterus, small vagina, and scaphoid perineum. On the other hand, cases of secondary involvement of the ovaries usually give a history of normal onset of puberty without severe spasmodic dysmenorrhœa, and quite commonly the patients have borne children prior to the onset of the menstrual irregularity. There are all varieties of endocrine disturbances leading to hypomenorrhœa, and I do not propose to go into them in any great detail. A common type is that in which the patient about the age of 30 develops adiposity, headaches, and irregular and scanty menstruation.

In all cases of primary ovarian deficiency, treatment should be directed along the lines of organotherapy. The results obtained are far from being satisfactory, but occasionally dramatic improvement has been reported. Of the ovarian hormones, œstrin is marketed in the forms of theelin, progynon, menformon, and sistomensin, and recently the British Drug Houses has put a more potent preparation on the market, 'œstroform'. Œstrin should always be given subcutaneously, for it has been calculated that subcutaneous injections are eight times more powerful than the same dose given orally. This leads to the inconvenience of a hypodermic injection. Another disadvantage is that only small doses are put up by the manufacturing chemists, and it is difficult to believe that any dose of the order of a hundred rat units is likely to have any lasting effect on an adult woman. If such doses are given they must be administered frequently, probably at least three times every week. The corpus luteum hormone, progesterin, is not marketed at present, so that so far as ovarian therapy is concerned only œstrin is available. On theoretical grounds the anterior pituitary hormone, by stimulating the ovaries to produce ripening follicles and corpora lutea, is to be preferred to the ovarian hormones themselves. The pituitary preparations that are available are the prolan preparations and antuitrin S. It should be remembered that here again the hormone must be given by injection, and it is essential that the substances should be freshly prepared. With the anterior pituitary hormone there is the same difficulty about dosage. Probably the ampoules that are put up by the manufacturing firms do not contain sufficient of the active principle to have any lasting therapeutic effect. In any case, if the injections are to be given they must be given frequently—at least three times every week. I carried out some clinical trials with œstrin some years ago and found that in cases of primary ovarian deficiency a good effect was obtained only in those of mild degree. There was little evidence that it had any good effect in severe cases, and I believe that this view is generally held at the present time. With the anterior pituitary hormone the results are not perfectly satisfactory, and it is wrong to suppose that the hormone has a specific effect in reducing the irregular cycle of cases of hypomenorrhœa to the normal cycle of twenty-eight days. In some instances of hypomenorrhœa, in which the patients also complain of sterility, dilatation of the cervix may be beneficial. For some reason or other dilatation of the cervix stimulates the generative organs and, as is well known, conception

frequently follows this procedure. Similarly, in cases of hypomenorrhea the menstrual cycle may revert back to its regular rhythm. This treatment is frankly empirical, and is based on clinical experience. Nevertheless, it is a valuable therapeutic measure in cases of hypomenorrhea, particularly if sterility is an attendant symptom.

Air Traffic in Relation to Public Health

By T. H. D. GRIFFITS

(Abstracted from the *American Journal of Tropical Medicine*, Vol. XIII, No. 3, May, 1933, p. 283)

At repeated sessions of the Permanent Committee of the International Office of Public Hygiene problems of the sanitary control of air navigation have received consideration, and it has increasingly become apparent that any set of just and reasonable regulations must be predicated upon facts established through researches and studies of factors relating to air traffic.

Realizing the necessity for investigations on the subject, the United States Public Health Service began on 23rd July, 1931, the inspection, for the presence of mosquitoes aboard, of all aircraft arriving at Miami, Florida, from foreign and insular ports. Strangely enough, the first mosquito caught was an *Aedes aegypti* (male) on 28th July, on the ship coming from San Salvador. From 23rd July to 12th September, 1931, there were 102 inspections of airplanes just arrived at Miami from points in Panama, Central and South America, the West Indies, Cuba and Mexico. On these planes a total of 29 mosquitoes was captured: one *Aedes aegypti* and twenty-eight *Culex quinquefasciatus*. Later inspections during the seasons of 1931 and 1932 have added to this list specimens of six other species.

This preliminary work in itself was sufficient only to determine the fact that mosquitoes were carried for some distance in aircraft of three different types—Trimotor Fokkers, Commodores and Sikorsky Amphibians. There was not established, however, anything definite as to how far these mosquitoes had travelled by airplane or how long they had remained aboard. In order to secure more definite information on these points, the United States Public Health Service carried out an experiment by staining and liberating *Aedes aegypti* on passenger planes of the Pan American Airways System at San Juan, P. R. Briefly the experiment and results were as follows: Several hundred *Aedes aegypti* were developed from larvae collected in San Juan and after feeding those that would take blood from the arm, batches of the adults (male and female) were stained with a 2 per cent solution of eosin in water, using a small atomizer to apply the stain through a gauze-covered cage. These specimens were liberated from the cage in all compartments of the 10 passenger Trimotor Fokker planes immediately before leaving for Miami, Florida, on 13th, 16th and 18th September. The time of leaving San Juan on each of these days was about 5-30 in the morning and arrival at Miami was approximately 4 o'clock in the afternoon, with an aggregate of about one and a half hours for stops at Santo Domingo, Port au Prince and Camaguey. The speed was approximately 125 miles per hour, and the maximum altitude reached on the flight about 5,000 feet. Each of these airplanes carried into Miami stained specimens put aboard at San Juan on the morning of the day of arrival in Miami. In the three experiments 100 mosquitoes were liberated on the planes at San Juan and 22 were captured after landing and unloading passengers, mail and baggage at Miami. It is, of course, possible, or even probable, that even a larger percentage of the mosquitoes put aboard came through, for one is not sure of having seen all mosquitoes and it is not always easy to catch all specimens seen. By these exact experiments, the first of record anywhere in the world, it was demonstrated that cabin planes carried mosquitoes for ten hours or more and for a distance of 1,250 miles.

Renewing the studies of last season, and adding more rigid tests of the capacity of *Aedes aegypti* to travel by airplanes, the United States Public Health Service, while continuing the routine inspection of planes for mosquitoes at Miami and inaugurating similar inspection service at Brownsville, Texas, undertook another series of staining experiments which was carried on, first from San Salvador, Central America and, later, from Cristobal, C. Z. The latter studies are still in progress.

Through hearty co-operation of the Pan American Airways System experiments on stained mosquitoes liberated on airplanes at San Salvador and destined for Brownsville, Texas, were begun by the writer at San Salvador in the latter part of April 1932. Reports are complete on the loading of 12 airplanes at San Salvador and the inspection of these planes at Brownsville. In the twelve batches of mosquitoes, total number of insects 840, liberated in all compartments of the planes, 69 specimens were captured on the planes at Brownsville upon arrival on the second afternoon following the departure of each plane from San Salvador. The average number of mosquitoes completing the trip was 8 per cent of the number put aboard at San Salvador. The average number of mosquitoes liberated in these stained batches was 70. The number captured at Brownsville on the planes ranged from one to 27, the average being 5.8 per plane. A brief description of this flight will be of interest. These are Ford Trimotor cabin passenger planes. They leave San Salvador Saturdays and Tuesdays at 7 A.M., and spend the first night in the hangar at Mexico City, with intermediary stops at Guatemala, Tapachula, San Jeronimo and Vera Cruz. On the second morning the plane takes off from Mexico City at 8-15 and arrives at Brownsville, Texas, at 12-55 P.M., with one intermediary landing at Tampico. The time consumed on the trip from San Salvador to Brownsville, Texas, is twenty-nine hours and fifty-five minutes. There are six intermediary landings, one of which is an over-night stop. The average maximum elevation reached on these trips is 14,000 feet, or more than 4,200 metres, proving that mosquitoes (*Aedes aegypti* at least) are not killed by such elevations. This elevation is one and three-fourths times greater than was reported in the Belgian experiments in sending mosquitoes in cages by air, in which it was thought high mortality was probably due to elevation.

At San Salvador we also liberated batches of stained *Aedes aegypti* on planes making trips to Miami, with a number of intermediate stops. On some of these flights the individual plane does not come all the way through. However, one plane on 8th June, 1932, left San Salvador at 7 A.M., made 10 landings and three over-night stops, arriving at Miami on the fourth day. Seventy stained specimens of *Aedes aegypti* were liberated in the plane at San Salvador just before leaving. They were put in the passenger cabin, in the cockpit and baggage compartments. Four of the stained specimens were recovered alive upon arrival at Miami. All were stained, all were gorged with blood and were from five to twelve days old. To date this is the longest time on record during which mosquitoes (*Aedes aegypti*) have been known to remain aboard an airplane on a trip seventy-nine hours and forty-five minutes in a flight from San Salvador, El Salvador, C. A., to Miami, Florida, with 10 intermediate landings, three of them over-night stops. The maximum elevation on this flight was 5,000 feet (1,524 metres) over Guatemala.

Between 28th June and 14th October, 1932, 15 cabin passenger planes on this route have been 'loaded' with stained *Aedes aegypti* at Cristobal (a few *Culex quinquefasciatus* have unavoidably been mixed with the mosquitoes stained). Approximately 840 mosquitoes were liberated on the fifteen planes, or an average of 56 mosquitoes per plane. Of the total number put aboard in the various compartments (mostly in the passenger cabin) 82 specimens, or approximately 10 per cent, were recaptured upon arrival at Miami. It should

be mentioned here that on several of these trips mosquitoes became so troublesome, especially to pilots, that an insecticidal spray was used in planes to kill the insects. Practically all mosquitoes were killed by the spraying. On one ship it was learned that a negro watchman, guarding the mail on board in the over-night stop at Kingston, 'was so troubled by mosquitoes' that he used the usual spray to kill the mosquitoes aboard. Contrasted with the results at end of trips on which it was known, or strongly suspected, that an insecticidal spray had been employed, was the ship that left Cristobal on the morning of 8th August. On 7th August, strict orders were issued from the office of the manager of operations that airplanes should not be sprayed to destroy the mosquitoes put aboard in the experiments being conducted by the United States Public Health Service. This plane arrived in Miami on the afternoon of 9th August—thirty-three hours and forty-eight minutes after leaving Cristobal, with a landing at Barranquilla, Columbia (S. A.), an over-night stop at Kingston, Jamaica, and a stop at Cienfuegos, Cuba—with 21 (35 per cent) of the 60 mosquitoes liberated on the ship at Cristobal. The maximum elevation reached on this flight is from 7,000 to 7,500 feet (2,134 to 2,287 metres).

Thirty Trimotor Ford passenger planes on regular flights between Cristobal, C. Z., and Brownsville, Texas, from 28th June to 11th October, 1932, carried a total of 1,610 stained mosquitoes, or an average of 54 mosquitoes per plane, on leaving Cristobal. Approximately two and a half days are required on this flight. The first night is spent at San Salvador, the second night at Mexico City, and Brownsville is reached at 12-55 on the afternoon of the third day—54 hours and 44 minutes after leaving Cristobal. As will be noted below, the percentage of mosquitoes recovered at the end of these flights falls far short of that on the Cristobal-Miami ships. The results more nearly compared with those on the latter route when planes are known, or suspected, to have been sprayed *en route*. Only 32 (2 per cent) of the 1,610 specimens put aboard at Cristobal were captured at Brownsville. No mosquitoes were caught on fifteen of these planes, while on the other fifteen the number recovered ranged from a single mosquito on each of six planes to a maximum of seven on one plane. It is probable that there was more routine spraying of these planes with an insecticide than occurred on the Cristobal-Miami planes.

In the series of experiments wherein stained specimens of *Aedes aegypti* were liberated on planes at San Salvador, C. A., and Cristobal, C. Z., between 4th May and 13th October, 1932, all specimens were developed from the larval stage, kept in cloth-screened cages, and allowed to feed on raisins and blood (for the females) from the arm of laboratory workers. Upon examining the recaptured mosquitoes at the end of trips note was made of gorged and ungorged specimens. A large majority of the female specimens recovered had partaken of blood meals. The ten specimens (all female *Aedes aegypti*) caught on Ford Trimotor plane No. NC 9688, leaving San Salvador on 12th June and arriving at Brownsville, Texas, after a flight of 30 hours and 55 minutes, with six landings and an over-night stop at Mexico City, were all blood engorged and well stained. As public health officials we are especially concerned with the transportation of mosquitoes that may be infected or infective. Since a large majority of the female mosquitoes used in these experiments had taken blood at least once, and in the above-mentioned experiment had taken blood fifteen or more days before, it is a safe conclusion that infected, or infective, *Aedes aegypti* may be carried from one country to another on flights of two days or longer.

It is thus shown that the known yellow fever and dengue vector of the Western Hemisphere may be carried with facility on airplanes from and to countries in which there were formerly endemic or epidemic centres. Comprehensive, but not too rigid, or unreasonable, sanitary regulations will be required in

the face of threatened introduction, through (1) proper surveillance of passengers and crews of aircraft coming from infected localities, (2) anti-mosquito sanitation at airports and their environs, and (3) proper precaution to prevent mosquito harbourage in aircraft and the destruction of mosquitoes on aircraft upon, or after, leaving airports. The same may be held true for other diseases transmitted by insects. The writer has observed house flies, honey bees and cockroaches on planes. In one experiment in the destruction of mosquitoes liberated on a Commodore passenger plane at San Juan, by the use of 'Zyklon B', in addition to the killing of all mosquitoes, the writer observed hundreds (estimated at 1,000) of cockroaches killed by the same exposure to the gas. The danger from rats and fleas carried in planes is not known. Rat droppings have been observed in airplanes, but the writer has no knowledge of rats having been found on planes.

In this brief paper some of the aspects of public health in relation to air traffic have been set forth. As stated in the original report on this subject, previously referred to: 'notwithstanding the fact that airplanes may, or do, transport mosquitoes, this mode of introduction of mosquito-borne disease' or any other insect-borne disease—'is probably secondary in importance to the importation of infected man', and 'while there is a recognized potential danger, there is no obstacle to the efficient treatment of airplanes so as to destroy mosquitoes and avoid retardation of air traffic progress'.

Calcium Thiosulphate in the Treatment of the Complications of '914' and Bismuth Administration in Syphilis

By A. E. W. MCLACHLAN, M.B.

(Abstracted from the *British Medical Journal*, 27th May, 1933, p. 916)

CALCIUM THIOSULPHATE was quite recently introduced into the therapy of post-arsenobenzol complications; it has been found especially effective in arsenical dermatitis. Sodium thiosulphate has been in regular use for this purpose for a dozen years or so, and for a much longer period calcium chloride has been used in cutaneous inflammatory conditions; theoretically, therefore, the combination of these two substances promises to be successful. The following cases of intolerance following either '914' or bismuth are recorded by the worker from his recent experiences:

(1) *Early arsenical dermatitis*.—Male, aged 31. Sero-negative primary syphilis. Developed arsenical erythematous dermatitis three weeks after completion of first course of '914' and bismuth. Calcium thiosulphate, 0.6 gramme intravenously, daily for three days, then at three-day intervals. Skin lesions completely clear on the thirteenth day.

(2) *Post-arsenical dermatitis*.—Male, aged 50. Persistent sero-positive syphilis. Developed exfoliative dermatitis, which was treated over a period of several months with sodium thiosulphate. Condition became stationary, with scattered areas of scaly, fissured, infiltrated skin over flexures of arms, legs and trunk. After twenty-two injections of calcium thiosulphate, at three-day intervals, the skin was completely clear.

(3) *Jaundice*.—Male, aged 49. Persistent sero-positive syphilis. Had post-arsenical jaundice in April 1932, which yielded after one month's treatment with sodium thiosulphate. Four months later treatment of '914' was recommenced.

December 1932, while under dual therapy. Calcium thiosulphate, 0.6 gramme intravenously, the first two doses on successive days, then at two-day intervals. Icterus completely clear after the fifth dose.

(4) *Immediate reaction (vomiting) after '914'*.—Male, aged 40. Persistent sero-positive syphilis. Vomited after each injection of '914'. No other signs of intolerance over a long period of treatment. Vomiting controlled by admixture of sodium thiosulphate; equally well controlled by calcium thiosulphate. Other

factors—bulk of injection, rate of administration, etc.—were kept as far as possible unchanged.

(5) *Bismuth dermatitis*.—Male, aged 49. Persistent sero-positive syphilis. Developed arsenical erythema while under dual therapy. This yielded rapidly to sodium thiosulphate. Bismuth administration recommenced two months later. After a course of 3 grammes metallic bismuth in ten weeks he reported with a scattered papulo-squamous erythematous rash on the trunk, with moist, fissured, eczematous lesions of serotum. The skin lesions partly cleared under the administration of sodium thiosulphate, but those of the serotum remained unaltered after bi-weekly treatment for one month. Calcium thiosulphate was then commenced. 0.6 gramme bi-weekly; the serotal lesions and the residua on the skin cleared up completely after five injections. That bismuth was an aetiological factor in the production of this dermatitis, in a skin previously damaged by an arsenical erythema, was proved by the recurrence of a similar rash on the re-exhibition of bismuth.

(6) *Dermatitis, probably due to bismuth*.—Male, aged 27. Sero-negative syphilis. Treated originally with '914' and mercury, then with '914' and bismuth. No '914' for three and a half months, during the last ten weeks of which he received 3 grammes metallic bismuth. In the eighth week of the bismuth therapy he reported a papulo-squamous erythematous dermatitis, which was aggravated by the subsequent injections. There had been no intolerance while under dual therapy, a total of 13.35 grammes '914' and 8.7 grammes bismuth having been administered. The dermatitis was considered to be due to bismuth, and treatment with calcium thiosulphate was instituted. After the seventh injection (0.6 gramme bi-weekly) the skin had completely cleared.

In one case of bismuth stomatitis the pain and discomfort were relieved by the administration of calcium thiosulphate, although clinically there was no improvement in the condition of the mouth. One case of seborrhœic dermatitis, which showed a tendency to flare up during the administration of bismuth, was markedly improved.

Apart from the feeling of intense heat in the skin, which comes on during or immediately after the injection, and persists only a few moments, the intravenous injection of calcium thiosulphate has been uneventful. Where it was possible 0.6 gramme was administered daily for three days, then injections were given twice weekly. Where sodium thiosulphate was given the first injection was 0.6 gramme, and subsequent injections 1 gramme.

CONCLUSIONS

The results of the calcium thiosulphate treatment of six cases of intolerance to '914' or bismuth are reported; in these cases calcium thiosulphate appeared to exert a definite curative influence.

Common Fungus Infections of the Skin

By C. HOWARD WHITTLE, M.A., M.D. (Cantab.)
M.R.C.P. (Lond.)

(Abstracted from *The Medical Press and Circular Supplement*, No. II, 5th April, 1933, p. xiii)

RINGWORM OF THE SCALP

It is well known that ringworm of the scalp is confined to children, and tends to disappear spontaneously at puberty, even in a case that remains untreated. The disease, which is highly infectious, starts as a circumscribed patch of scurf in which broken hairs appear early. Whitfield maintains that any marked scurfiness in a child's head should be regarded as ringworm until the most careful search and microscopic examination has proved it to be otherwise. This axiom is well worth remembering. Infected hair stumps can often be detected more readily if a little chloroform is dabbed on the patch; this causing them to appear

granular and 'frosted'. Broken hairs should be sought for, and if found the diagnosis can be established by microscoping in liq. potasse, in which they should be soaked for ten minutes. The spores are readily visible as a mosaic of round, highly refractile bodies, regular in size and structure, and situated in and around the hair. The only bodies likely to cause confusion under the microscope are red blood corpuscles and oil globules. The former are present in scanty numbers unless violence has been used in removing hairs, and should offer little difficulty: they are much less refractile than the spores. Oil globules, on the other hand, may be numerous, but vary very greatly in size, from tiny particles up to large droplets. For those who have not the time or the facilities for microscopy, a suspicious case is best sent to a dermatologist, since treatment will have to be carried out by a specialist in most cases.

While dealing with the subject of diagnosis there are two points I would stress. Confusion may arise between a patch of dandruff or psoriasis and ringworm, and between alopecia areata and ringworm. In dandruff and psoriasis there are no broken hairs, and in alopecia areata the broken hairs are typically shaped like an exclamation mark (!), and do not show the corrugated frosted appearance of ringworm hairs when treated with chloroform, neither do they contain spores. Difficulty most often occurs when the bald patch is scurfy. The differentiation is important, since complete epilation as a cure for alopecia areata is hardly the treatment one would choose. Whereas for ringworm it is the only really reliable measure. The point is not one of mere academic interest. I have had several cases of alopecia in children sent to me as ringworm for epilation.

There is one form of ringworm of the scalp, 'black dot' ringworm, which is very apt to be mistaken for alopecia areata, but as it is rare the difficulty does not often arise. In this form the bald patch is not scaly, but the hair follicles are not empty as in alopecia, and contain the remains of a hair broken off very short, and usually black in colour. This hair contains the fungus: a large-spored endothrix, not the microsporon.

The other point in diagnosis which I wish to stress is the immense help afforded by the use of a blue filter on an ultra-violet light lamp for showing up hairs infected with ringworm. In this light the hairs fluoresce brilliantly. I have been able to track down a carrier of ringworm in a school by this means when other measures and methods of examination had failed; and while epilation is taking place, it is my practice now to examine the cases each week to see that all the infected hairs fall. Even a single infected hair can be detected in a head of hair otherwise healthy. A number of clinics now use the lamp as a routine. Diagnosis is certain, and is made with great rapidity.

A form of scalp ringworm in which these filtered ultra-violet rays are not, however, of much service in diagnosis is the boggy, indolent pustular swelling known as kerion. This is commonly an inch or so in diameter, purple in colour, with pus exuding from deep indentations—the hair follicles—the hair itself being usually absent. The inexperienced may be strongly tempted to put a knife into this in order to release pus from what in some ways appears to be an abscess. But the pus is not free, and incision will be useless; moreover, the swelling and inflammation are the natural means of cure, and no treatment is as a rule needed beyond encouragement with 1–4,000 perchloride of mercury compresses.

For the forms of ringworm of the scalp other than kerion, dermatologists are agreed that x-rays are the most certain and most rapid means of producing epilation, which is essential before the disease can be eradicated. Other methods of epilation, with the exception of thallium acetate by the mouth, are, in Whitfield's words, 'dirty, painful and tedious', and if they are to succeed, require special skill in their carrying out.

Nowadays, with the aid of the filtered ultra-violet light, it is possible to define accurately the extent of

the disease, and epilatory doses of x-rays can therefore with safety be limited to the affected parts provided the case is followed up and watched for two months. I believe in the efficacy of applying an anti-parasitic ointment during the fall until all the hairs have fallen: it prevents loose fragments of hair falling about on to clothes, etc., and inhibits the growth of fungus on the scalp surface. During the fall, white cotton caps should, however, be worn in addition, and washed every other day. The ointment I use is Whitfield's:

Acidi benzoici	gr. 25
Acidi salicylici	gr. 15
Paraffini molliis	dr. 2
Oleum cocois nucifer. ad.	oz. 1

With regard to thallium acetate, many workers have used it and found it efficacious in many series of cases. I was unfortunate in my first trial of this drug, since the child was certainly not well during the fall, going off its food and looking pale and wan. I have employed it in a few cases since, and always with success. (It is given in a single dose, and the amount given is in strict proportion to the child's weight.) The indications are in those cases where x-rays cannot be given owing to the early age of the child (under four or thereabouts), or where for other reasons the child cannot be induced to keep still during the epilatory dose. In spite of these successes, I dislike using the drug owing to its undoubtedly poisonous nature.

RINGWORM OF THE GLABROUS SKIN

The difficulty in eradicating scalp ringworm depends upon the position of the fungus within the hair follicle and shaft. Drugs will not reach the spot in sufficient strength to kill the fungus without seriously damaging the skin. When ringworm occurs on the open skin the problem is usually a much simpler one.

Clinically, there are four chief forms of ringworm met with on the skin. The first, *trinea circinata*, is a microsporon ringworm which occurs on the skin of children who are, almost without exception, the subjects of scalp ringworm. The rings are pinkish in colour, slightly raised and finely scaly, are usually not more than an inch in diameter, and occur on the neck, shoulders, face, and sometimes on the arms. The scales contain the fungus. There is a large form somewhat similar, but which is not caused by the microsporon, and occurs independently of scalp ringworm; this is less common.

Another form which is seen quite commonly in agricultural communities, and which is the predominant form seen in the out-patient department in this district, is the rather heaped-up, indolent, oedematous circular patch which occurs on the face, neck, arms and hands of workers who tend cattle. This, by its firm, raised, indolent, usually painless character, often suggests an infective granuloma such as a gumma, or even in some cases actinomycosis. Usually it is possible to trace the follicular origin, and pus that may be expressed comes from the lanugo follicles. In this or the lanugo hair it is possible to find the fungus, a large-spored type, of which the spores are oblong, and are usually arranged in chains. The diagnosis is easily made once the possibility has entered the mind of the practitioner, and those practising in agricultural districts soon acquire a familiarity with it. A history of association with cattle gives the clue. I have occasionally seen this form on the arms and legs of children, and it is possible that infection takes origin from fences and gates on which the children play, and on which cattle may frequently be seen rubbing themselves; at least this seems to me a likely explanation in the absence of a history of direct contact with infected animals.

A third important form which has been much more prevalent since the War is *trinea cruris*, or dhobi's itch. This form occurring in the groin and perineum as sharply marginate, scaly, itchy erythematous patches is also common in Cambridge, but for quite another reason. It appears in undergraduates, who usually bring

it with them from the public schools. It is a highly contagious disease, and often spreads widely in schools. Clothing, towels and baths are probably the means of spread, and boys are apt to be careless in these matters. It is not, however, confined to boys and young men, but may occur in persons of all ages. I recently saw a case in a lady, eighty years of age, which had puzzled her doctor for some weeks. Infection in such a case is possibly *via* a lavatory seat.

The older name for this form was *eczema marginatum*. It may present a raw, weeping surface, instead of the more common, dry scaly characters, but the important feature leading to a diagnosis is the sharply defined marginate nature of the lesion. It may be several inches in diameter. The scales show an abundance of the fungus in the form of a long, branching, fairly stout, mycelium. Liq. potassæ preparations show it well.

A fourth form caused by the same organism is the intertriginous ringworm found between the toes, causing a sodden, reddened, scaly, sharply marginate lesion running a slow and chronic course. This form also appears to be increasing in frequency, and in America investigations indicate that spread is from person to person in the footways of swimming baths. This type usually affects the cleft between the little toe and the next, and may spread to adjacent clefts and involve the distal part of the foot, both dorsum and sole. It frequently remains localized to one foot, and this feature, when present, is in favour of the diagnosis, and against a non-infective eruption. The mycelium can usually be found without much difficulty in the scales. The same fungus may cause a vesicular eruption of the hands not unlike cheilopompholyx. The fungus can be demonstrated in the roofs of the vesicles.

The occurrence of generalized eruptions, secondary to the local affection, and known as trichophytides or epidermophytides, has been noted in recent years. One form very like lichen spinulosum occasionally occurs in connection with epidermophytosis of the feet. An undergraduate came to me for the treatment of a patch of horny follicular spines appearing on the extensor aspect of the forearms, and it was not until I made special inquiry that I discovered a lesion of the toe clefts, which examination proved to be due to ringworm. The treatment of the latter undoubtedly played a part in clearing up the trouble on the arms.

The treatment of body ringworm is simple, and most lesions clear up in a week or so under either 1-4,000 mercury perchloride compresses, which are specially suited to the heaped-up cattle types, or Whitfield's ointment for most of the others. Toe ringworm may require double strength ointment, and it is important to clip away the frayed scaly edges, and keep the toes separated. More resistant cases of toe ringworm will respond to 1-2,000 warm baths of potassium permanganate twice daily (Whitfield). Ultra-violet light is cumbersome, and usually unnecessary for treating body ringworm. Simpler methods are to be preferred.

RINGWORM OF THE BEARD

This commonly manifests itself as a circumscribed boggy patch on one side of the face, with some pustulation in the follicles. The fungus, which is a large-spored type, can be found in the pus or hair stumps. The differential diagnosis from syecosis of staphylococcal origin presents certain difficulties. The latter is less heaped up, less boggy, and less frankly pustular, and runs a more chronic course. Usually beard ringworm will yield to mercury perchloride compresses. X-ray treatment will cause resolution in resistant cases.

RINGWORM OF THE NAILS

One or more nails on one hand may be affected, and the nail is much coarsened, longitudinally ridged and thickened. Scrapings must be soaked twenty-four hours in potash before the fungus is visible under the microscope. X-ray treatment offers the most rapid method of cure, but some cases may be very resistant to treatment.

TINEA VERSICOLOR

This condition shows as a yellowish-brown discoloration of the skin, usually the trunk, with a sharply defined edge. It may extend in a sheet across the trunk, or may occur in patches only. The lesion is not visibly or palpably raised, and may not even be scaly.

I have had patients referred as cases of Addison's disease on account of the pigmentation, but the discoloration is all on the surface of the epidermis, and, if the horny layer is scraped off, the fungus *Microsporon furfur*, is found in abundance as mycelium, club-shaped bodies, and spores. The condition is not very infectious, as a man may have it for years and not give it to his wife. It clears up readily with Whitfield's ointment.

Observations on the Cure of Malaria with Atebrin

By A. L. HOOPS, C.B.E., M.D., N.P.H.

(Abstracted from the *British Medical Journal*, 10th June, 1933, p. 993)

THE PROBLEM IN MALACCA

THE population with which my colleagues and I deal consists of over 19,000 rubber estate labourers and dependents, and of the staff—European and Asiatic—with their households, numbering over 800, who control the estates.

TREATMENT OF MALARIA WITH ATEBRIN

For the actual treatment of malaria reliance has hitherto been placed on that old and tried remedy quinine. On European estates the sufferer from primary malaria has received full doses in hospital for perhaps ten days, followed by smaller doses, for perhaps three weeks, in the lines. He has been given more quinine when at labour inspections he has been found to possess an enlarged spleen. And yet, with all this dosing, it is well known that over 50 per cent of sufferers so treated relapse and have further attacks of malaria, in some cases repeatedly, and for years after the original infection. There are several notable disadvantages attending the use of quinine such as the long continuance of the treatment, the difficulty of carrying this out, the lowering effect on the vitality of its continued administration, the great liability to relapse, and, finally, the expense.

Beginning the trial of atebrin in June 1932, I have found that it has apparently brought about a permanent cure in the great majority of 153 malaria cases treated by me between that month and the end of the year. Two of my colleagues, Dr. I. D. Stubbs and Dr. Foo Hce Seng, who started to use the drug in August 1932, have had similar results among 163 cases treated by them. Our combined figures are:

Total cases treated	TYPE OF MALARIA				Relapses
	Subtertian	Benign tertian	Quartan	Unclassified	
317	98	114	5	100	11

Eighteen of the ninety-eight patients under the heading 'subtertian' were cases of mixed infection, showing benign tertian parasites as well. In four subtertian cases, in which cerebral symptoms appeared, I administered from two to six doses of quinine bihydrochloride intramuscularly, with one death. The 'unclassified' patients were mainly on estates where no microscope was available, but were clinically cases of malaria. The figures for relapse up to the end of March 1933—that

is, over nine months after the first case and three months after the last case was treated—are eleven. The relapses usually occurred within two months of the first treatment, the types of malaria in which these were noted being subtertian (three), benign tertian (two), unclassified (six).

Relapse rate

There is little movement among labour forces at present, and it has therefore been possible to keep in touch with the great majority of those treated. Deducting, however, the liberal allowance of 20 per cent from the total 317 patients treated, on account of persons since lost sight of, there remain 253 treated and still under observation, with eleven relapses—a relapse rate of 4.34 per cent. All persons once treated with atebrin and having further malarial attacks have been counted as relapses, though some may have been fresh infections. Of the eighteen cases of mixed infection, eleven occurred on one division, where there was a violent outbreak of malaria due to a temporary failure in oiling—thirty-eight out of a population of sixty-seven being affected within one month. Microscopical findings were: fourteen subtertian (of whom eleven showed benign tertian parasites also) and twenty-four benign tertian. In spite of so many double infections, there has not been a single relapse on this division, though seven months have passed since treatment was given.

Death rates

A comparison of the labour death rates among those treated in hospital with quinine and with atebrin respectively is of interest. In 1931, 934 cases of malaria were treated in hospital, all with quinine: 10 grains of the sulphate or bihydrochloride were given in solution three times daily for nine or ten days, followed usually by small doses of quinine in the lines for three weeks. Deaths numbered thirty-one; death rate, 3.31 per cent. In 1932, 288 patients were treated in hospital with quinine, of whom fourteen died; death rate, 4.85 per cent. Of the 317 patients who received atebrin, 257 were treated in hospital, with four deaths—a death rate of 1.55 per cent. Both the relapse rate and the mortality rate, therefore, favour atebrin treatment. Of the labour population, averaging 19,511 last year, two-thirds were Southern Indians—mostly Tamils—less than one-third were Chinese, and about 1,200 were Malays; 55 per cent of those treated with atebrin were Tamils.

Staff treated

In addition to labour, eight Europeans, including two ladies, and ten members of the Asiatic staff were treated for malaria with atebrin in the last half of the year 1932. All found it easy to take, and experienced a sense of well-being after it. None has so far relapsed.

Particulars of treatment

A course of atebrin lasts as a rule for five days only. The daily amount administered is 0.3 gram (4½ grains) for adults and for children over 11, 0.1 to 0.2 gram (1½ to 3 grains) for children of 5 to 10 years, and 0.035 to 0.1 gram (½ to 1½ grains) for children of 1 to 4 years, and is given in three divided doses. In addition, plasmoquine is prescribed in subtertian cases only, also for five days—0.03 gram (½ grain) daily for adults in three divided doses; children of 11 receive only half this dose of plasmoquine, and younger children proportionately less. The bowels are kept freely open throughout. The tablets of atebrin and plasmoquine are crushed and taken with a drink of water half an hour before meals. Most patients are also dosed with oil of chenopodium to remove their ankylostomes, and those who need it have santonin to relieve them of round-worms. At the conclusion of the treatment patients are placed on an iron and arsenic tonic. No quinine has been given with atebrin by me, except by injection in a few severe cases.

ADVANTAGES OF ATEBRIN

The points in favour of the use of atebtrin in place of quinine are:

(1) The fever is usually reduced as quickly as with quinine; it is uncommon to find a temperature above 99°F. after forty-eight hours' treatment. In two cases only did fever persist as long as the fifth day; for these atebtrin was continued for eight days.

(2) With the exception of subtertian gametocytes, it is rare to find malarial parasites in the blood after the second day of treatment. No parasites of any description were found in the blood of any hospital case on the conclusion of treatment.

(3) The treatment is short, simple, and effective—one 1½-grain tablet three times a day for five days only, as against a prolonged course of quinine.

(4) The drug is not unpleasant to take, and is not depressing. It is well tolerated, even by pregnant women and young children and in blackwater fever, and also by persons suffering as well from other diseases such as pneumonia and influenza.

(5) Relapses are rare after atebtrin, while with quinine the relapse rate is high.

(6) The cost of a course of atebtrin (fifteen tablets) is about 75 cents (1s. 9d.), that is, less than the cost of a course of quinine—one ounce, about \$1 (2s. 4d.)—not to speak of the cost of treating the frequent relapses when quinine is used.

(7) In malaria of the benign tertian and quartan types atebtrin only is necessary.

(8) When malaria is subtertian in type it is necessary to give a five-days' course of plasmoquine in addition to atebtrin (cost about 43 cents, 1s.), but this is also needed when quinine is employed, as subtertian gametocytes are unaffected by either quinine or atebtrin.

(9) Last, but not least, atebtrin is a powerful preventive of malaria in the sense that most of those treated with it, being cured, are rid of the infection and completely non-infective to their fellows. It may well prove that the regular use of atebtrin—plus plasmoquine in subtertian cases—for the cure of malaria will lessen the amount spent on antimalarial drainage and oiling.

LIMITATIONS OF ATEBRIN

Are there any serious disadvantages in the use of atebtrin? So far as my experience goes, 'No'. A few patients have colicky pains about the last day of treatment, and a few show a temporary yellow discoloration of the skin and conjunctiva, due not to jaundice, but to the fact that atebtrin contains a yellow dye. No form of the drug suitable for injection is yet available; consequently, in very severe cases of malaria, it is advisable to administer one or several doses of quinine, generally by intramuscular injection. Some medical men, though now using atebtrin for malaria, are prescribing quinine during the first two days of treatment. This may be quite sound, but personally I have as far as possible employed atebtrin alone in order to test fully the value of that drug without quinine.

In a progress report issued locally in November 1932, R. Green states that both benign tertian and quartan parasites, including gametocytes, disappear from the blood more quickly with atebtrin than with quinine. In subtertian malaria the rings disappear either with quinine or with atebtrin in about three days. The febrile period in all types is slightly shorter with atebtrin than with quinine, but, pending the cessation of febrile symptoms, the temperature among some of the subtertian cases seems to remain on the whole somewhat higher, and the patient to be more prostrate, than with quinine. The subtertian infection varies from the very mild case to the fulminating case, attended with fatal results whatever the form of therapy. In the small but certain proportion of subtertian cases which show alarming symptoms, Green regards it as at present advisable to administer quinine for two or three days as a preliminary to atebtrin.

Green's relapse rates

Among forty-three patients who had 30 grains of quinine bishydrochloride a day for seven days, and were under observation for a maximum of forty-six days, Green's record is:

	Total cases	Relapses
Benign tertian	.. 12	6
Subtertian	.. 13	5
Quartan	.. 18	5

Among forty-eight cases receiving a six-days' course of atebtrin, and kept under observation for a maximum of eighty days (seventeen being benign tertian, twenty-three subtertian, and eight quartan), Green observed one relapse—a benign tertian case on the thirty-second day after treatment.

CONCLUSION

The treatment of malaria with atebtrin is short, simple, and economical. Most sufferers appear to be cured within a week. The consistent use of this drug should effect a great and permanent diminution of malaria among labour forces by sterilizing most of the reservoirs of infection.

The Use of Digitalis other than in the Treatment of Cardiac Decompensation

By HENRY A. CHRISTIAN, M.D.

(Abstracted from the *Journal of the American Medical Association*, 18th March, 1933, Vol. C, No. 11, p. 789)

CARDIAC HYPERTROPHY, instead of being a beneficent process, is an injurious influence on cardiac function; the heart, once enlarged, is already on its way to eventual decompensation: to retard hypertrophy is to prolong cardiac efficiency.

Clinical observation has taught that with few exceptions the enlarged heart rarely recedes in size and that sooner or later the enlarged heart shows signs of inefficiency. It may be taken as a clinical dictum that cardiac hypertrophy with rare exception is the first evidence of cardiac failure, though it may long antedate any symptoms or signs of cardiac insufficiency. If one considers that type of heart disease which is most frequent in adults, so-called chronic myocarditis, chronic non-valvular heart disease or chronic myocardial insufficiency, whatever term one prefers to use for this condition, it will be found that the foregoing statement is unqualifiedly true.

If, then, as I believe, cardiac enlargement is functionally harmful, intelligent therapeutics will seek to retard it. It is generally believed that increased demand on cardiac function serves to increase cardiac enlargement, and so clinicians advise patients with enlarged hearts to decrease their physical exertion. Can anything else be done in the way of treatment? I believe that just here digitalis has a definitely desirable effect, and if given daily in moderate dosage it will retard cardiac enlargement and delay the appearance of symptoms and signs of cardiac insufficiency. Consequently I advise patients in whom I find enlargement of the heart to decrease physical exertion and to take continuously from 0.1 to 0.15 gm. of digitalis leaves twice daily, unless this amount causes toxic symptoms, as occasionally it does. If that happens, the dose is reduced to a point at which no toxic symptoms appear. Digitalis for these patients is continued throughout the remainder of life. The optimum dose is that just below the one which eventually produces toxic manifestations, a dose to be determined by the method of trial and error.

USE OF DIGITALIS

If cardiac insufficiency has developed to a point to produce symptoms and signs marked enough to interfere with the individual comfort and activities, it is said that cardiac insufficiency has developed or that the heart is decompensated. Rest and digitalis is the

practically universally instigated therapeutic management of such cases. In a large percentage so treated, symptoms and signs of cardiac insufficiency very largely disappear. With return to a greater degree of physical activity, sooner or later a return of the same symptoms and signs is to be expected. Clinical experience indicates that, if to such patients a daily ration of digitalis, short of toxic effects, is given, this return of evidences of cardiac insufficiency will be delayed. Consequently it has become a quite general practice to give such patients digitalis continuously in amount just short of toxicity, the proper amount approximating 0.15 to 0.25 gm. daily of powdered digitalis leaves, the exact amount being determined by the method of trial and error, some patients tolerating more and others less than this daily ration in the sense of being just short of toxicity. This elsewhere I have termed the continuation treatment with digitalis.

Now if digitalis, thus used as a continuation treatment, is helpful under the circumstances just enumerated, it is reasonable to suppose that, if given in this way prior to the development of symptoms and signs of cardiac insufficiency, development of these symptoms and signs might be delayed. My own clinical experience seems to be in accord with this idea, and so I have come to give digitalis in this way to patients in whom I can detect evidences of cardiac disease, particularly cardiac enlargement. It does seem as if cardiac enlargement is retarded and that these patients are capable of greater activity without having symptoms or signs of cardiac insufficiency than are patients otherwise similar not receiving digitalis.

There are certain individuals in whom, although there is no detectable evidence of cardiac enlargement, one can feel quite certain that sooner or later enlargement of the heart will take place. The most numerous in this group are individuals with hypertension and next in frequency come those who have developed a diastolic murmur of some sort or who, with a past history of rheumatism, show a systolic murmur without any murmur in diastole. The query naturally occurs in light of what I have just been saying. Why not give digitalis to such individuals?

Certain observations of pharmacologists investigating digitalis have a bearing on this suggestion. At one time it was believed that digitalis would cause cardiac hypertrophy, but many experiments have shown that this did not occur. Cloetta noted that animals receiving digitalis over long periods of time had even lighter hearts than those receiving no digitalis. Furthermore, he found that, if aortic insufficiency was produced, animals subsequently given digitalis had hearts both smaller and more efficient than did animals with similar aortic lesions not receiving digitalis. Here is experimental evidence in favour of the clinical thesis that I have just enunciated in regard to beginning digitalis even prior to the development of hypertrophy in those patients in whom hypertrophy may be expected to develop.

Observation has shown that in the aging process the heart muscle loses water. Other observations show that one effect of digitalis is to increase hydration in heart muscle. This points to a probable therapeutic effectiveness of digitalis for elderly patients not to be expected in the young. Heart disease due to myocardial insufficiency is most frequent in the later decades of life. Clinical experience points to a particular usefulness of digitalis in just this group of individuals, those past middle life (40 to 50), with cardiac enlargement without valve lesions, not yet having symptoms or signs of cardiac decompensation. Competent observers believe further that in elderly people with no evidence of cardiac enlargement but in whom circulatory efficiency is lessening, digitalis increases heart efficiency, and here digitalis possibly may be said to have a definitely 'tonic' effect, presumably increasing the hydration, which has decreased in the aging process.

Pharmacologists have demonstrated a certain automaticity in the regulation of digitalis effects that help in the treatment of patients with cardiac enlargement.

Digitalis, before it exerts any digitalis effect, is fixed in the heart muscle. After fixation in the heart muscle it is split up into an inert carbohydrate and a substance that produces a digitalis action. This fixation varies directly with the concentration of digitalis circulated to the heart muscle and with the bulk of the heart muscle but indirectly with the rate of circulation through the muscle. These laws of digitalis action influence the effectiveness of digitalis therapy. As the heart enlarges, all other factors being unchanged, a given dose of digitalis has an increasing effectiveness in ratio to the increasing bulk of the myocardium. As the myocardium loses in efficiency, the circulatory rate in the coronary system of vessels is slowed. As a result of this, more digitalis is fixed in the heart muscle fibres and this causes an increased digitalis action. In other words, within certain limits, an automatic increase in digitalis action occurs under just those circumstances that would need a greater digitalis action and that without any increase in size of dose. As heart action improves, circulatory rate through the myocardium accelerates and fixation of digitalis decreases, thus bringing about a lessened effect from a given dosage than would be the case were there not this relationship. In other words, when there is more need for digitalis, digitalis is proportionately more effective, and when the need decreases, the same dose of digitalis has less effectiveness. This saves the clinician from the necessity of continuously changing digitalis dosage to meet changing function of the heart muscle.

VALVULAR HEART DISEASE

What has been said about non-valvular forms of heart disease applies, too, to valvular types of heart disease except that since valve lesions occur chiefly in younger people, in whom heart muscle has not lost water, the action of digitalis on heart function is less effective than when given to older persons. Also, as valve lesions introduce an unchangeable mechanical factor decreasing heart efficiency, again not so striking an improvement is to be expected from giving digitalis to these patients. However, since there is no harm caused by giving digitalis, it is reasonable to give it, too, in valvular heart disease as just advised for non-valvular heart disease both prior to and subsequent to the appearance of symptoms and signs of cardiac decompensation. It seems probable, however, that here it will not be as useful as with non-valvular forms of heart disease.

LONG CONTINUED DOSAGE

Digitalis for the conditions just being discussed is continued over very long periods of time. Obviously, if a drug is to be taken daily over long periods of time, it is essential that the drug has no harmful effects, direct or indirect, that it has no habit-forming qualities and that from continuous use it does not lose its effectiveness. There is no pharmacologic or clinical evidence that any of these things happen. Repeatedly have I seen the patient who has been taking a daily dose of digitalis for weeks and months respond to an increased dose indicated by reason of developing evidences of cardiac decompensation, in just the same way as a patient with similar evidences of cardiac failure who had received no previous digitalis therapy.

If one will stop to think of the way digitalis acts, it will be seen to be an ideal drug, pharmacologically, for long continued dosage. Digitalis given by any route or dosage reaches the heart muscle, where it is promptly fixed or bound. In a short space of time it commences to be split within the muscle into a part that has digitalis action and an inert part. This splitting is a gradual process, long continued, very slowly decreasing in the degree of digitalis action on the heart muscle. Before one dose has ceased to act, another can be given, which in its turn will be fixed and split and continue a digitalis effect. It is entirely possible on account of this way of action to space properly sized doses of digitalis so as to maintain a digitalis action throughout the twenty-four hours with but little fluctuation from hour to hour.

in the intensity of that action and to continue it practically indefinitely from day to day by suitable doses not closer together, let us say, than twelve hours. Could there be a more ideal mechanism for maintaining a therapeutic effect over very long periods of time? In this respect digitalis has a part almost like the replacement therapy of thyroid gland substance in myxœdema, insulin in diabetes mellitus and liver extract in pernicious anemia, for all of which physicians say to their patients, you must continue taking this daily so long as life lasts.

The Problem of Relapse in Chronic Pulmonary Tuberculosis

By R. C. WINGFIELD, M.B. (Oxf.), F.R.C.P. (Lond.)
(Abstracted from the *Lancet*, 3rd June, 1933, Vol. I, p. 1166)

By relapse I do not mean merely the reappearance of symptoms, but I mean the appearance, and often the sudden appearance, of definite fresh lesions in those parts of the lung where no lesion was demonstrable before. I certainly do not mean the insidious direct spread of lesions already present.

STUDY OF A PARTICULAR CASE

I have tried to make a special study of these relapses and have been fortunate enough during the last few years to have seen a good many. I am sorry to think how many I may have overlooked. Of these I propose to describe one fairly typical case which will illustrate many of the clinical features that I have learnt to associate with these relapses, and to argue as from that.

A. C., a big strong boy of 20, had a left artificial pneumothorax, induced in the Brompton Hospital, to which he made an excellent response. He was sent to Frimley and went through his sanatorium course without relapse. He was afebrile, with a normal pulse rate, had no cough or sputum, and made a good gain of weight. When ready for discharge he stayed on, doing heavy manual work on the sanatorium pig farm in return for board and artificial pneumothorax treatment.

This consisted of a full eight-hour day of heavy physical work, and he kept in splendid health without symptoms or loss of weight for one year. One day he developed a common cold in the head with all its usual symptoms and slight fever. His temperature rose to 100°F. on the first day and settled to normal by the seventh day, and I would like to point out the mildness of the pyrexia and its rapid disappearance. Also it is important to note that his symptoms were slight and, beyond the reappearance of sputum non-localizing further, that they rapidly disappeared. An x-ray was taken, although there was no marked change in physical signs. His previous film showed a collapsed left lung and a right lung clear of disease; the new film showed a dense hazy opacity the size of the palm of the hand in the right subclavicular region. In fact, a new lesion of considerable size had appeared in his right lung. He was kept on complete rest for one month, during which time all symptoms and constitutional disturbance disappeared and he seemed perfectly recovered, but since a further x-ray at the end of that time showed no clearing of the new lesion, a selective right-sided artificial pneumothorax was induced, and he has been back now at the same work for 12 months in excellent health.

Now it will be instructive to picture what would probably have happened in his case had he been fully discharged from the sanatorium, and had not been an artificial pneumothorax case, and as such under close supervision. He would have reported to his tuberculosis officer and have been found to have done well and probably advised to go back to work and to report at stated intervals. He keeps well, but one day he

gets this cold, and, as a keen hard-working boy, he would probably have ignored it altogether, or perhaps would have taken one day off work. If it had happened in between his visits to his tuberculosis officer, the latter would probably have heard nothing at all about it. The symptoms disappearing rapidly, he would carry on blissfully unconscious of this new lesion. How long? One cannot say; it may be only for a short time, but experience tells us that it may be many months before definite symptoms from this new lesion appear and cause the patient to seek medical advice. If there are some residual symptoms from the previous lesions the visit to the doctor will probably be longer delayed. Much depends on the patient's intelligence and outlook, and on the efficiency of the individual dispensary's control of its cases. But in any event it is unlikely that the tuberculosis officer will see him until this 'secondary' lesion (if I may be permitted to use my own terminology) has turned into a well-entrenched irreparable damage is done—treatment starts again—and handicapped treatment. For my experience of these 'secondaries' is that if they are caught young and energetically treated, often by rest alone, they can usually be healed. The same cannot be said of an 'intermediate'.

THE ALLERGIC REACTION

To go back to some pathological considerations. I have stated elsewhere my belief that these fresh areas of disease are due to an hematogenous deposit of tubercle bacilli in the interstitial tissue of the lung, setting up around themselves an allergic reaction of simple acute inflammation. If this is true, the x-ray shadow that appeared in this case had a small core of tuberculosis and a large capsule of simple acute inflammation which cast the main shadow. The fate of this composite lesion depends partly upon the patient's individual resistance to tuberculosis, partly on his environment or treatment, and partly on the intensity of the allergic reaction. The allergic reaction has been assumed to be beneficial; it may be so to some extent, but not entirely. In support of this I quote A. R. Rich, who has devoted so much time to the study of allergy. He says:

'The damage done by allergy in this disease is very serious indeed. A great part of the tissue destruction in tuberculosis is due to hypersensitivity to the protein of the tubercle bacillus. The prevention of this damage by means of desensitization might be of great service to many tuberculous patients. I am thoroughly aware of the virtue of inflammation as a protective mechanism. I question here only the virtue of that excessive inflammation accompanied by necrosis which characterizes the allergic reaction..... Allergy converts the comparatively harmless protein of the tubercle bacillus into a virulent poison.'

To return to our composite lesion, either the whole thing heals leaving a minimal scar, or, as the simple inflammation subsides, the tuberculous core spreads into the damaged or necrosed surrounding tissue, and we are left with an active spreading 'intermediate' lesion. I believe that the time this lesion takes before it produces symptoms depends on two factors, (1) the rate of spread, (2) the erosion of a patent bronchiole which throws the lesion open to the fauna and flora of the respiratory tract, and permits secondary pyogenic infection to complicate the pure tuberculosis. We see from day to day so many cases who can tolerate the tubercle bacillus and its lesions without symptoms and without constitutional disturbance that it seems we must postulate something of the sort to explain why some patients get all the classical symptoms and others do not. This one example from many cases that I have studied illustrates, I am certain, what happens to the great majority of those cases who do badly after routine institutional treatment when they might have done well. Incidentally, it is the story of the reasonably early case, or indeed almost any case, presenting himself for his first diagnosis.

FIVE SALIENT FEATURES OF RELAPSE

It may be well to review the position and underline the five salient features of relapses of which C's case may be taken as a fairly typical example. These five features are as follows:

- (1) These relapses have no obvious prodromata.
- (2) The new deposit may in some cases be entirely silent; in most cases the symptoms and constitutional disturbance that accompany it are so slight that they can be too easily ignored; occasionally it is accompanied by a severe reaction.
- (3) In many cases physical examination conveys but little information, and if the new deposit is accompanied by physical signs these are often evanescent.
- (4) The symptoms and constitutional disturbance are usually of very short duration and disappeared completely.
- (5) There is an indefinite latent period before the second reappearance of symptoms. And I should like to add that these again will often yield to the mildest treatment.

If it can be agreed that these relapses are a common cause of our ill-success, how shall we meet the problem? The obvious answer is to have much closer clinical and x-ray control for the critical two years after institutional treatment. For facts tell us that neither routine institutional treatment nor its adjunct collapse therapy will protect our patients with any certainty from these new lesions. But such a suggestion is rather like the tardy shutting of the stable door. For although it is true that a fresh lesion will usually respond to treatment excellently if caught early, it does necessitate further treatment. This is distressing and discouraging to the patient, often-times forcing on him mental, social, and financial hardship and imperilling his already slender chances of getting, or keeping, a wage-earning job. For the country, too, it is economically unsound. We should if possible find a means to prevent these relapses.

The sensitiveness or the allergic state of the patient gives us a clue. Allergy and immunity are two entirely different things. I think Professor Leroy Gardner has expressed this very happily when he says 'Allergy and immunity are created by the same condition—i.e., the experience of infection—but their subsequent courses are not necessarily parallel'. But since the greater part of these lesions is, I believe, a simple allergic inflammation, beneficial perhaps in some respects but at the same time an excellent hotbed for the spread of their tuberculous core, I believe that if we can render our hypersensitive patients less sensitive we shall to a great extent protect them. And in this belief I have the theoretical backing of Rich in the excerpt I quoted above.

SENSITIVENESS AND DESENSITIZATION

If this conception is correct, one reason why one patient relapses and another of the same type and under the same environment does not is because the one is more sensitive than the other. Consider these figures from the South African Institute of Medical Research (Rept. XXX, vol. 5, 1932). Of 93,979 natives presenting themselves for enrolment in the mines, 61,115 were found to be already infected by giving a positive Mantoux reaction to a 1/5000 dilution of old tuberculin. Of these, 3,879 gave a ++ response—i.e., were highly sensitive—while 57,236 gave a simple + response—i.e., were less sensitive. Among the highly sensitive the incidence of subsequent clinical tuberculosis—mostly, I think, pulmonary—was 1.03 per cent, while among the less sensitive it was a little more than half that, 0.65 per cent. I am fully prepared to have Heimbeck's experience of the nurses and students at Oslo quoted against me here, but the two situations are entirely different. Heimbeck was dealing with the problem of primary tuberculous infection and resulting clinical disease in non-infected people exposed to the bacillus for the first time. The South Africans, and we, are dealing with the problem of the likelihood of the appearance of secondary pulmonary tuberculosis, and its

subsequent relapses, in a previously infected population.

For a great number of our successfully treated cases one of the important factors in their prognosis, then, is their degree of sensitiveness. If this is high they are in greater danger than if it is low. I am fully aware that their degree of immunity is probably as, or even more, important a factor. We are, however, woefully ignorant of tuberculo-immunity, so at present we cannot attempt to influence it. But animals, and again I quote Rich as my authority, can be desensitized by tuberculin, and we know that man can be desensitized to tuberculin by tuberculin. This therefore seems the logical course to pursue.

Desensitization to large doses of tuberculin is a perfectly safe procedure if carefully controlled, and since it would entail much closer clinical control of the ex-institutional patient I can see but little argument against it. At the worst it can only be a waste of time. There are many things one would like to know. Is the degree of sensitiveness a variable quality, or is one person always hypersensitive and another always hyposensitive? If sensitiveness does vary in the individual from time to time what factors govern this variation? It is extremely interesting to find that it does vary widely in different persons, irrespective of their clinical or pathological condition at the time of making the test. If a person is desensitized, how temporary or how permanent is the loss of allergy is another important question to answer.

Along these lines an attempt is being made to prevent relapse in immediately successfully treated cases. We shall have to wait, I am afraid, at least five years, more probably ten, before results can be tabled.

Sodium Dehydrocholate in Arsphenamine Poisoning

By BERNARD APPEL, M.D.

(Abstracted from the *Archives of Dermatology and Syphilology*, March, 1933, Vol. XXVII, p. 401)

(1) ARSPHENAMINE in therapeutic doses is rapidly metabolized in the liver.

(2) After the lethal dose of arsphenamine, the liver contains a maximum amount of arsenic and is apparently the only organ of storage.

(3) One hour after a lethal dose of neoarsphenamine, all parts of the lobules of the liver are loaded with arsenic.

(4) Twenty-four hours after a lethal dose of tryparsamide, the liver begins to show degenerative changes.

Thus, most of the damage to the liver is apparently done within the first few hours after the administration of the arsenical. It seems logical to state that symptoms related to this damage could be controlled if this early storage of arsenic could be prevented. If it were possible to produce an increase in the rate of excretion of bile and to maintain this for some hours following the injection of an arsenical, this would constitute a washing-out process during which it would be difficult for arsenic to become stored.

There are two types of reaction to the arsenicals that are related to liver metabolism: one is jaundice; the other is the gastro-intestinal reaction characterized principally by nausea and vomiting. The latter may occur either immediately after the injection, occasionally even before the needle is withdrawn, or may be delayed for a number of hours. These two types of reaction are disturbing and are prominent causes of reluctant cessation of the use of arsenicals in cases in which they would otherwise be definitely indicated.

In a study by Stokes and others, of 3,244 patients with syphilis treated with arsphenamine, gastro-intestinal reactions developed in 7.49 per cent and jaundice in 2.34 per cent.

Pertusal of the current literature disclosed work in Europe along the line of prevention of these reactions with sodium dehydrocholate.

Dehydrocholic acid was developed in 1881 by Hammarsten and introduced for clinical use by Neubauer in 1923. It is an oxidation product of cholic acid, one of the bile acids. The sodium salt is freely soluble in water, is weakly alkaline in reaction and has a bitter taste. It differs principally from cholic acid in being practically non-toxic. The salts of taurocholic and glycocholic acids have a degree of toxicity which precludes them from intravenous use.

Administered intravenously, sodium dehydrocholate causes definite increase in the quantity of bile excreted. This effect is most marked within the first thirty minutes after injection and continues for a total of about ninety minutes. The only known contraindication to its use is absence of bile in the stools.

C. Costinescu, of Bucharest, treated seventy-six syphilitic patients with large doses of arsphenamine (15 mg. per kilogram of body weight) by mixing the arsphenamine solution with 5 c.cm. of 20 per cent solution of sodium dehydrocholate before injection, without encountering toxic reactions.

A. Șavulesco also reported a number of cases in which the patients were treated with very large doses of arsphenamine mixed with a solution of sodium dehydrocholate. He concluded, among other observations, that sodium dehydrocholate decreases the toxicity of the arsphenamine.

Hans Abelsolm reported the cases of seven patients in whom jaundice developed during the course of injections with neoarsphenamine, but whose treatment was successfully continued by mixing the subsequent injections with sodium dehydrocholate solution. He stated that this solution should be given in cases of jaundice whether the condition is due to syphilitic involvement of the liver or to arsenical poisoning.

In the five cases of jaundice and in the case of gastrointestinal reaction herewith reported, the patients were treated with sodium dehydrocholate administered intravenously. The patients were all being treated for syphilis in the out-patient department; they had all received varying amounts of neoarsphenamine intravenously.

REPORT OF CASES

Case 1.—A white man, aged 69, married, was admitted to the hospital on 1st April, 1932. Jaundice developed while he was being treated with neoarsphenamine. On admission he was given an intravenous injection of sodium thiosulphate as the use of sodium dehydrocholate had not been instituted at that time, and on 8th April, intravenous injections of the latter were begun. The patient received a total of 105 c.cm. in eleven injections.

On 6th May, the patient was discharged to the out-patient department feeling well but with a mild residual jaundice. One noteworthy effect of the treatment was a marked increase in appetite. This occurred in almost every other case of jaundice in which similar treatment was given.

Case 2.—A white man, aged 24, single, was admitted to the hospital on 31st March, 1932. He had previously been in the hospital from 12th March to 24th March, 1932, because of arsphenamine hepatitis. An infection of the upper respiratory tract had developed, which was still present; a recurrence of jaundice was also noted. Treatment was started with one intravenous injection of sodium thiosulphate and dextrose, but a week later injections of sodium dehydrocholate were begun.

The patient was discharged to the out-patient department on 6th May feeling well and symptom-free, except for a slight residual jaundice.

Case 3.—A white man, aged 52, married, was admitted to the hospital on 2nd April, 1932. He had been treated with neoarsphenamine, and jaundice had developed. He was given one intravenous injection of sodium thiosulphate at entry. Soon after this, injections of sodium dehydrocholate were started. While in the hospital, the patient complained of vague abdominal and peripheral

pains, which were considered to be related to the syphilitic involvement of the central nervous system. The Wassermann test of the spinal fluid was positive, as was also that of the blood.

He was then transferred to a state institution for further antisyphilitic treatment, the jaundice having improved markedly.

Case 4.—A white man, aged 44, single, was admitted to the hospital on 14th April, 1932. He had been treated with neoarsphenamine in the out-patient department for syphilis. Jaundice had developed, and before admission he had received several intravenous injections of sodium thiosulphate.

Although still somewhat jaundiced, the patient was discharged at his own request, in order that he might return to work. He felt well and was to report to the out-patient department for further treatment.

Case 5.—The patient was a white woman, aged 23, married, who had been treated for syphilis with neoarsphenamine. Jaundice had developed one week before admission. She was discharged feeling well but with a residual jaundice.

A pertinent question is whether sodium dehydrocholate has any vitiating effect on the pharmacologic action of the arsphenamine. The case which follows answers this by showing that a syphilitic lesion of the tongue progressed favourably under treatment with a combination of sodium dehydrocholate and neoarsphenamine. In this patient a gastro-intestinal type of reaction developed.

Case 6.—A white man, aged 23, married, had been treated for syphilis in the out-patient department. Before his admission to the hospital, the first injection of neoarsphenamine, 0.3 gm., caused no reaction; after the second injection of 0.45 gm. nausea and vomiting occurred, which lasted two days. He then went to a private physician for further treatment. After the next injection of neoarsphenamine, 0.45 gm., given by his doctor, vomiting, fever, slight jaundice, fainting spells and mild mental disturbance occurred.

Following this upset, he was referred to the house service by his physician. On admission, he was slightly jaundiced and somewhat disoriented as to time and place. There was a punched-out, active, syphilitic lesion on the tongue and ulcerated, membranous lesions of the throat.

The patient was given five injections of neoarsphenamine, the dosage being 0.3 gm. The first dose was mixed with 10 c.cm. of 20 per cent sodium dehydrocholate. He complained of a bitter taste and vomited immediately after the injection, but felt well thereafter. The subsequent four injections were mixed with 10 c.cm. of 5 per cent solution and were not accompanied by any disturbance. The tongue and throat cleared up almost entirely, and he was discharged eighteen days later to his private physician, who gave him three injections of neoarsphenamine, the dosage being 0.3 gm., and each dose being mixed with 10 c.cm. of a 5 per cent solution of sodium dehydrocholate. There were no subsequent reactions. The doses of neoarsphenamine were all made up with distilled water in a strength of 0.15 gm. to each 5 c.cm. of water.

Not all patients with the same type of reaction as that of the patient whose case has just been reported have done so well. Of eight others, one apparently received no benefit from the treatment, and one had doubtful benefit.

SUMMARY

Sodium dehydrocholate is a choleric drug, non-toxic in doses of 10 c.cm. of a 5 per cent solution administered intravenously at intervals of several days.

It has been used to combat the toxic action of arsphenamine and its derivatives on the liver.

In five cases of jaundice which developed during antisyphilitic treatment with arsphenamine the patients were treated with sodium dehydrocholate. There was a prompt fall of the icteric index, with rapid recovery. No explanation is given at this time, but it is suggested that the effect may be

caused by the washing of arsenic from the liver, owing to increased choleræsis.

In a number of cases in which nausea and vomiting followed intravenous injections of neoarsphenamine, the patients were treated by mixing the solution of the drug with a solution of sodium dehydrocholate and injecting the mixture intravenously. The majority of the patients showed no reactions following these injections. One case is reported in detail.

CONCLUSION

By the use of sodium dehydrocholate administered intravenously, two types of reaction to neoarsphenamine can be combated, jaundice and the gastro-intestinal reactions of nausea and vomiting. This is of utmost value for patients requiring vigorous treatment for an active syphilitic infection, as the reactions would ordinarily prohibit the use of arsenicals.

The Diagnosis and Treatment of Subacute Combined Degeneration of the Spinal Cord

By T. KAY MACLACHLAN, M.A.

M.B. (Camb.), F.R.F.P.S.

(From the Medical Press and Circular Supplement, 26th July, 1933, p. xv)

INTEREST has been renewed in this condition during the last six years following the great advance in treatment of Addison's (pernicious) anaemia by liver and its extracts, as initiated by Minot and Murphy; more especially as the prognosis of this nervous disease, so often associated with pernicious anaemia, had formerly been extremely bad.

Subacute combined degeneration of the cord is a condition named from its histological picture. Degenerative changes are seen in the posterior and lateral columns of the cord, and in advanced cases practically all the white matter of the cord may show absence of myelin, while the brain also may show some shrinking due to demyelination, especially in the fronto-parietal regions. The disease tends to commence in the mid-dorsal segments of the cord where the blood supply is poorest; it is thought to be of a degenerative rather than of an inflammatory or a vascular nature, and the striking feature is the absence of the neuroglial overgrowth which takes place in other conditions of the cord whether they be of inflammatory or degenerative origin. The condition is frequently associated with Addison's anaemia, but may also occur with severe anaemia due to other causes, with lymphatic leucæmia, and with cachetic conditions.

Although subacute combined degeneration of the spinal cord is established as a definite clinical entity, yet combined disease of the afferent and efferent system of the cord may occur in association with several conditions, namely, disseminate sclerosis, Friedrich's ataxy, meningomyelitis, myelitis, lathyrism and pellagra, as well as in some syphilitic conditions where changes in the cord produced by interference with the vascular or lymphatic circulation may cause a similar picture.

One should not now be satisfied with a diagnosis of 'spastic paraplegia', or 'ataxic paraplegia', although these were included till recently, in some textbooks, as diseases of the nervous system.

Subacute combined degeneration of the cord was formerly thought to be a late association of pernicious anaemia, and while it is true that symptoms referable to the nervous system, especially numbness and tingling in the extremities can be found in the majority of patients suffering from pernicious anaemia, it must be remembered that similar symptoms may occur in any severe anaemia or cachetic state, and that one is not justified in diagnosing subacute combined degeneration on the presence of any nervous symptoms, even though there is no doubt clinically about the diagnosis of pernicious anaemia.

The criteria on which subacute combined degeneration has been diagnosed probably to some extent accounts for the extreme variations described by different observers in the response to treatment. It must, however, be remembered that subacute combined degeneration may be quite definitely present before there is any evidence clinically, or even hematologically, of pernicious anaemia, as ignorance of this point appears to be the reason why certain cases are so very far advanced before a diagnosis is made.

The diagnosis is not always straightforward, as the clinical picture varies, dependent on the relative affection of the posterior columns, pyramidal tracts, or peripheral nerves.

The earliest symptoms are usually paresthesiæ, numbness and tingling in the lower limbs, and later the patient is aware of some clumsiness and weakness, and becomes less steady on the feet. Sensory examination shows some loss of vibration and joint sense, with perhaps some diminution in sensation to pressure and light touch. Less commonly there are pain, formication or a feeling of icy coldness, but lightning pains resembling those of tabes have been described. Later a girdle sensation, which may even be painful, develops and paresthesiæ also affect the hands.

It is usual thereafter to get involvement of the motor system, with a history of the limbs becoming easily tired, and later of one or both being dragged and feeling stiff, and this, with exaggerated deep reflexes, a positive Romberg's sign, clonus and extensor plantar responses, led to the condition being formerly known from its clinical features as ataxic paraplegia.

When the paraplegia becomes marked, dysuria is usually noted, while if untreated the paraplegia becomes complete, and the trunk and arms are also involved, although usually the shoulder and upper arm muscles are little affected. In the later stages wasting of the muscles with loss of electrical response occurs, and a flaccid paralysis with absent knee-jerks, but an extensor plantar response, is seen, and there is incontinence of rectum and bladder. Less frequently the picture is one of flaccid ataxy with early loss of reflex activity, and evidence of posterior column involvement, but even in these flaccid cases an extensor plantar response is usually obtained.

In the typical cases the sensory loss commences at the periphery, and tends to be of a glove and stocking distribution, while when it extends upwards to reach the trunk, its progress is usually limited by segmental lines. Trophic changes are common when the disease is well established, and bed sores are then difficult to prevent. Vasomotor disturbances at the periphery of limbs also occur, and oedema is occasionally seen.

In the advanced case, evidence of involvement of the cerebrum is not uncommon, being evidenced by confusion, drowsiness, and occasionally by delirium. Changes in the pupils and their reactions also occur, nystagmus may be present, and optic atrophy is occasionally observed, while if the disease has reached the lower cervical region involvement of the sympathetic fibres may be noted.

There may be no evidence of Addison's anaemia, but this is exceptional, it being usual to find at least megalocytosis with high colour index. The tongue often indicates an existing or previous glossitis, but even a history of a painful tongue or recurring digestive upsets are of value in helping to confirm one's diagnosis. For further confirmation, the fractional test-meal should never be omitted, especially if the blood examination is not helpful, as complete or relative achlorhydria is found in practically all cases.

DIAGNOSIS

If when first seen the patient presents the picture of an ataxic paraplegia with some loss of postural and vibratory sensation, various conditions have to be excluded. Tabes, as well as specific meningomyelitis, must be eliminated by a routine examination of the spinal fluid as well as of the blood.

In support of a diagnosis of disseminate sclerosis there would be a more rapid onset, and one would look for a history of diplopia, or of transient paresis, blindness, paræsthesia, or sphincter involvement; while nystagmus, absent abdominal reflexes, intention tremor or other lesions suggesting scattered involvement of the nervous system would be of confirmatory value. A paretic or luetic colloidal gold reaction in the spinal fluid in the absence of other evidence of syphilis would be of further diagnostic help.

If the girdle sensation or root pains were striking in addition to paraplegia and sphincter trouble, new growth of the spinal cord or its coverings would have to be excluded. Evidence of segmental sensory loss with perhaps a level of hyperalgesia, as well as pain and limitation of movement of the vertebra, should call for x-ray examination of the spine, and this, together with Queckenstedt's test and examination of the spinal fluid for xanthochromia and for dissociation between the amount of albumin and the cell count, should establish or exclude the possibility of tumour. Lipiodol radiography is occasionally helpful.

In elderly patients the occurrence of paresis and paræsthesia in the lower limbs as a result of vascular degenerative changes interfering with the nutrition of the spinal cord must be considered.

The age at onset, the family history, as well as nystagmus and skeletal deformities, help to distinguish Friedrich's ataxia from subacute combined degeneration, while residence abroad, a diet containing lathyrus sativus, and the simultaneous occurrence of several cases would suggest that lathyrism was the cause of the paraplegia.

Pellagra is uncommon in this country, but a history of a deficient dietary, and the characteristic lesions of the skin, as well as the affection of the nervous and alimentary systems and the tendency to exacerbations in the spring of the year, should establish the diagnosis. It must be remembered, however, that the disease may occasionally occur without the cutaneous lesions.

TREATMENT

There has been considerable difference of opinion as to whether liver, which is usually of such signal value in Addison's anemia, is of comparable value in subacute combined degeneration of the cord. Some writers have claimed that all signs and symptoms of cord disease may disappear, while others have found liver ineffective, not only in causing no material improvement, but even in staying the advance of the disease.

We have already noted that the picture of degeneration of the spinal cord may precede any outward clinical evidence of pernicious anemia, and in these days when the anemia can be so easily and quickly controlled by liver at its onset, the dose of liver necessary for the treatment of anemia *per se* need not be large for long. The failures in liver treatment of subacute combined degeneration of the spinal cord can often be traced to the employment of only those doses of liver which have been found sufficient to produce blood regeneration.

To treat the neurological condition it is essential that the liver must be pushed to a greater degree, and at the onset it should be given both in the form of one of the intramuscular injections as well as by mouth, and both fresh liver and the extract should be administered by the latter route. As in pernicious anemia, the response is better if the patient is able to take the fresh liver uncooked, and the daily dietetic routine can be made easier by the employment of the various recipes for the preparation of liver which have been published by Florence Irwin.

In combined degeneration of the cord one cannot be satisfied with a definite reticulocytosis, and an increasing red cell count as indication that improvement in the nervous condition is occurring. It must be our object to waste no time in arresting the changes in the spinal cord, and it has been found that a red

cell count of five millions is the standard at which one expects improvement in the cord symptoms, and not until this figure has been obtained should intensive liver therapy be discontinued. Nevertheless, one cannot expect regeneration in cases where nerve fibres have been destroyed, since nerve tissue cannot regenerate; but many of the symptoms have only been caused by the pressure of the swollen myelin sheaths and intensive liver therapy, even in cases only diagnosed when the condition is well-established, can usually relieve some of the symptoms. There are now many preparations of liver extract for oral administration on the market, and the equivalent of half a pound of liver as well as the same amount of the fresh gland should be given daily.

Following Gänsslen's production of extracts, potent by intramuscular or intravenous injection, the proprietary preparations Campolan and Hepatex are now available, and at the onset the equivalent of 500 grams of fresh liver should be given daily by injection.

Formerly in cases with marked anemia not diagnosed until an advanced stage, blood transfusion was often required, as the patient's anorexia and enfeebled general condition made adequate liver therapy by mouth impossible. Now even if the nature of the nervous disease is not recognized until the anemia is marked, transfusion is seldom necessary, or even intravenous injection, as an ampoule of campolan twice daily intramuscularly is usually sufficient to initiate a remission.

The rise in the cost of mammalian liver since its value in anemia has become generally known, and the greater expense of the liver extracts has made treatment a serious economic problem in the case of sufferers from subacute combined degeneration of the cord, where treatment must be pushed to a much greater extent than in pernicious anemia. In this connection the work of Davidson, in Aberdeen, in the preparation of a fish-liver extract promises to be of great value, as this extract has been found to be much more potent and more rapid in action than mammalian liver, while the cost to the patient should be much less.

Ventriculin, or other preparation of hog's stomach which has a similar effect to liver in promoting blood regeneration, may be used in place of a liver extract, but, as with the latter, it must be pushed to a greater extent than in treating anemia alone, and 30 to 40 grams daily should be given. The same remarks, however, do not apply to brain, which has been found to be of some value in inducing blood regeneration.

In treating pernicious anemia, Ungley found that the potency of brain in producing increase of the reticulocytes and red cells is only a third that of liver, but as regard the effects on the nervous system, brain has been found by him to produce definite neurological improvement in doses which would have relatively little effect compared with liver on blood regeneration. Brain is most potent given raw, and can be administered in the form of purée flavoured with tomato or orange juice. A dosage of about 480 grams daily should be employed.

More recently Sargent, maintaining that some cases of subacute combined degeneration were not improved by liver therapy, and that simple achlorhydric anemia might be the cause of the persistence of neurological symptoms in certain cases, discarded liver therapy in favour of massive doses of iron, and from this treatment excellent neurological results were reported, and even hematological improvement took place in some patients when liver had been found to be ineffective. In these cases (simple achlorhydric anemia) Bland's pill in doses of 150 grains daily may be used, and such an amount is usually well tolerated, even for the usual period of two or three months, before a reduction is made to a maintenance dose of 30-40 grains daily. It has been suggested that pernicious anemia and subacute combined degeneration of the spinal cord are deficiency diseases, and Mellanby has experimentally produced a condition similar to subacute combined

degeneration, even with mental affection, by diets deficient in vitamin A. He was able to relieve the neurological condition by incorporating vitamin A or carotene in the diet.

Strauss and Castle have shown that in pernicious anæmia there is absence of a normal 'intrinsic factor' in the gastric juice. Normally this factor acts on protein in the diet to produce a hæmatopoietic hormone, and the latter reacts with an essential 'extrinsic factor', believed to be vitamin B₁₂, to cause hæmatopoiesis. By further experimental work they conclude that vitamin B₁₂ is the extrinsic factor necessary for hæmatopoiesis, and that deficiency of vitamin B₁₂ is the cause of the neurological symptoms. These investigations have led to the employment of yeast, which contains vitamins B₁ and B₁₂, in the treatment of pernicious anæmia and subacute combined degeneration of the cord. For those unable to take ordinary yeast regularly this difficulty has been overcome by giving marmite, which is much more palatable, and a teaspoonful of this preparation should be given daily in sandwiches or added to gravy, while as a further variation bemax can be employed. If the diet does not contain adequate vitamin A, then the latter can be supplied by giving avoleum, radiostoleum or adexolin.

More recently Morris and his assistants have shown that a hæmatopoietic response can be produced in pernicious anæmia by the intramuscular injection of gastric juice. The antianæmic substance, 'addisin', which is probably a hormone, is destroyed by heat, and the juice has to be concentrated by distillation *in vacuo*. Amounts of this concentrate equivalent to 300-500 c.c. of gastric juice, while shown to be potent in the treatment of the anæmia, have yet to have their value proved in subacute combined degeneration of the cord.

Apart from what may be considered the specific treatment of the disease, there are other therapeutic measures directed to conditions frequently associated, which if ignored lessen considerably the efficacy of the methods we have already mentioned. Fever is not uncommonly present during the course of Addison's anæmia, and it does not appear to inhibit the action of liver, but if it is actually caused by any inflammatory or septic process such as cholecystitis, cystitis, or bedsores, then one finds definite inhibition of the normal response of neurological symptoms to treatment.

As in all nervous diseases, it must first be ascertained whether the bladder is functioning normally, or whether there is a bacilluria or pyuria. Direct questions must be asked in this connection regarding any dysuria, and it is well, even if the patient appears to be passing urine freely, to pass a catheter and find if there is any residual urine, as retention and decomposition of such often initiates a cystitis. Urinary antiseptics or lavage may be necessary.

Bedsores are of much worse import, especially if associated with incontinence of urine and feces, and if diagnosis and treatment have been delayed they often precipitate a fatal issue. Any focal sepsis, whether in skin, teeth, nasal sinuses, or elsewhere must receive treatment, and constipation must, of course, be controlled.

Some patients with subacute combined degeneration manifest evidence of hypothyroidism with malar flush, dry scaly skin, deficient perspiration, increased sensitivity to cold, and lowered B.M.R., and much general improvement may follow the administration of adequate doses of thyroid. The gastric deficiencies should also be made good, and the following mixture should be taken in a tumbler of water with the three main meals of the day:

R. Acid hydrochlor. dil.	dram 1-2
Glycerin pepsin	dram 1
Syr. lemonis.	dram ½
Aq. ad.	oz. ½

If there is indication of intestinal decomposition, the administration of charcoal or diinol after meals may be helpful, while abdominal massage, recumbency after meals, or a supporting belt should be advised if there is evidence of visceroptosis. Massage and passive movements are of value in spastic cases, or in those debilitated by long residence in bed, and re-educative exercises are of the greatest help to those patients who have improved to the extent of commencing to walk again, as well as for those whose hands had become clumsy for fine movements.

The outlook of patients suffering from subacute combined degeneration of the spinal cord, formerly so hopeless, has been greatly improved within the last few years, but diagnosis still tends to be made too late to obtain the full advantage of the therapeutic measures now available.

Reviews

CORRECTION

FUNGUS DISEASES: A CLINICO-MYCOLOGICAL TEXT.—By H. P. Jacobson, M.D. London: Baillière, Tindall and Cox, 1932. Pp. 317, with 153 illustrations. Price, 31s. 6d.

We regret that in our issue of June last, p. 353, when our review of the above book was published the price was stated to be 3s. and it should have been 31s. 6d.

Editor, I. M. G.

PHYSICAL CHEMISTRY OF LIVING TISSUES AND LIFE PROCESSES.—By R. Bentner, M.D., Ph.D. London: Baillière, Tindall and Cox, 1933. Pp. x plus 338, with 79 figures. Price, 29s.

The author has considered life as a scientific problem and, in attempting to study the problem in its various aspects, he has had recourse to the methods of colloid and electrochemistry—two of the main branches of physical chemistry. By preparing different artificial imitations of various single phases of life, he has tried to elucidate some of the most important problems of physiology, mainly connected with electrical currents in tissues and their relation to life processes. The book is made still more attractive because in its concluding

chapters it indicates in a clear manner the lines of future research in this direction, with the probability of enormous fruitfulness. If one requires further proof of the already established fact that methods of physical chemistry are essential for future researches in physiology, one is advised to read this book. It is needless to mention that the book will be of immense help to both physiologists and physical chemists.

R. N. C.

CAUSAL FACTORS IN TUBERCULOSIS.—By F. C. S. Bradbury, M.D., D.P.H. Published by The National Association for the Prevention of Tuberculosis, Tavistock Square, London, 1933. Price, 2s., post free.

The book contains 126 pages and embodies the report of an enquiry into the increased incidence of tuberculosis in certain Tyne-side districts in England. The National Tuberculosis Association financed the enquiry and Dr. Bradbury, a tuberculosis officer of the Lancashire County Council, conducted it. The investigation shows the stamp of thoroughness and care necessary for an intensive study of tuberculosis in a limited area, and brings forward, with the help of modern statistical

methods, the relative importance of economic, sociological and medical factors which may predispose to a high incidence of tuberculosis.

The two towns selected were Jarrow, which had a tuberculosis death rate of 2 per 1,000, and Blaydon where the rate was half of this. A house-to-house visit was made for collecting the necessary data on such factors as over-crowding, under-nourishment, insanitation, occupation of tenements, race, effect of early marriage, size and composition of family, poverty and house-to-tenant infection, always keeping as controls some non-tuberculous families. The clinical forms of tuberculosis prevalent in the area are analysed in part II of the monograph.

It has been shown that poverty has a marked statistical association with tuberculosis and that the chief methods by which poverty is found to cause tuberculosis are over-crowding and under-nourishment. The association of tuberculosis with poverty is greater than with most of the other factors studied. Over-crowding occupies a high position in the list of factors which contribute to the prevalence of tuberculosis in the areas dealt with. The standard of over-crowding has been taken as two or more persons living in one room. If the average income per head per week is less than ten shillings, families have been classed as poor. If the allowance per head per week has been less than one pound each of meat and butter and one pint of milk per head per day, the families have been labelled as under-nourished. Families of five or more persons have been classed as large families. A woman who married before the age of twenty-one has been regarded as having married early and is referred to as a young mother.

By following these standards it has been found that under-nourishment, particularly with regard to meat, bread, butter and fresh milk, is an important predisposing cause of tuberculosis and, in fact, of sickness in general. It has been further suggested that of the food-stuffs mentioned, fresh milk is of greater importance than the others as a preventive of tuberculosis in an urban population.

Over-crowding occupies a high position in the list of factors associated with tuberculosis, but it is not well understood as to why this is so.

Analyses of racial peculiarities have shown a considerable Irish element which forms about fourteen per cent of the population in Jarrow and only three and a half per cent in Blaydon, and it has been shown that there is more tuberculosis in Irish than in English families. After eliminating such correction factors as the relative size of families, it was found that earlier age and sex constitution are of little importance when compared with English families in which the mortality is much lower. Hence the conclusion has been drawn that the cause of the higher incidence of tuberculosis in the Irish is a relative want of immunity or racial susceptibility to the disease.

Conditions such as insanitation, bad ventilation, dirt, damp, house-to-tenant infection and the local peculiarity of women marrying at an unusually early age have been studied as being possible contributory factors but, though they may be of some importance as predisposing causes of tuberculosis, it is considered that their association with tuberculosis can be adequately explained on other grounds.

The investigation has brought to light the important fact that the supervision exercised by maternity and child-welfare clinics is a definite factor of importance in the suppression of tuberculosis. It has been noted that tuberculosis is more prevalent in families with children than in families without children, and is more prevalent in large than in small families.

Part II of the report deals with the findings from the clinical details regarding 1,033 patients who were on the registers of the Jarrow and Blaydon tuberculosis dispensaries between 1926 to 1930. It has been noted that the excessive mortality from pulmonary tuberculosis in Jarrow is especially marked in the 0 to 15 and 15 to 25 age groups, particularly in the former. In

females the maximum mortality occurs in the 15 to 25 age group, as in England and Wales. But the maximum in males in this area (Jarrow) occurs also in the 15 to 25 age group, thus differing markedly from England and Wales, where the maximum occurs in the 45 to 65 age group. It has been further found that the population of Jarrow suffers from a more rapidly fatal type of the disease. It has been suggested that the principal factors causing this are the relatively greater susceptibility of the population and the unfavourable home conditions. The high death rate from pulmonary tuberculosis in the 0 to 15 age group has been thought to be due to the unfavourable environmental condition prevalent in the area.

Non-pulmonary tuberculosis has been found to show certain peculiarities in Jarrow, particularly the unusually high incidence of abdominal tuberculosis. From the very limited use of fresh milk in the area it is thought that the high incidence of pulmonary tuberculosis is the chief contributory factor to the high incidence of non-pulmonary tuberculosis, largely owing to the increased opportunities for infection which occur through over-crowding and other adverse factors which are so prevalent in Jarrow.

The following conclusions arrived at by the committee will be found of practical value in reducing the incidence of tuberculosis:—

(1) The building and use of tenement dwellings should be strictly controlled, particularly in regard to the size and number of rooms, the number of persons who occupy them and the general sanitary condition of the dwellings.

(2) In view of the apparent importance of under-nourishment as a predisposing cause of tuberculosis, it is desirable that attempts be made to improve the defences of poor families against tuberculosis by providing adequate and balanced diets at the cheapest possible rates.

(3) Fresh milk, free from tubercle bacilli, especially in poor families, children, should be regarded as a daily dietary.

(4) The facilities provided by maternity and child-welfare clinics should be more widely used. The aim should be to have the fullest possible liaison between the Maternity and Child Welfare and Tuberculosis Departments.

The numerous conditions, which have been shown in the report to be associated with tuberculosis, suggest that collective action can deal with the disease at the source, whereas the ability of the individual to protect himself against it is more limited. The association's policy of active propaganda, to educate the public in matters concerning tuberculosis, has been thought a very necessary and valuable means of combating the disease.

We draw the attention of all workers who are interested in the question of the causation and prevention of tuberculosis, to this report which we consider to be a valuable contribution to our knowledge of some factors underlying differences in the incidence and character of tuberculosis in various areas. We join with the committee members in hoping that this report may stimulate the organization of similar intensive investigations in other areas. The work already done in rural and urban areas by us in India strikingly agrees with several of the findings of the committee.

A. C. U.

'STUDIES IN THE PHYSIOLOGY OF THE EYE'.
Still Reactions: Sleep: Dreams: Hibernation: Repression: Hypnosis: Narcosis: Coma and its Allied Conditions.—By J. Grandson Byrne. London: H. K. Lewis and Co., Ltd., 1933. Pp. xii plus 416, with 47 illustrations. Price, 40s.

A BETTER title for this most interesting book would have been 'Studies in the Physiology of Vision', using the word Vision in its widest sense. The book will appeal not only to physiologists and ophthalmologists but also to psychologists. In this last group are included

all those practitioners who are interested in the mental health of their patients. In fact it is mainly for this last group that the book has been written and the following extract from the last paragraph of the final chapter illustrates this.

The author is referring to the results of his experiments spread over a period of twenty years and he says:—

'They also, in my opinion, furnish the means for a better understanding of the physiological processes that underlie, or are associated with all mental activity, and consequently may furnish in addition the solid foundation for a therapy-preventive and restorative based upon psychoanalysis—which shall not be too mystifying or metaphysical, but scientific and practical, and above all available for extensive use by the medical practitioner.'

And that in the reviewer's opinion is just exactly what is wanted in these days. Each chapter is followed by a summary of the results of the experiments which is both lucid and convincing and each summary is followed by an exhaustive bibliography.

H. S. C.

DIABETES IN CHILDHOOD AND ADOLESCENCE.—

By Priscilla White, M.D. Published by Henry Kimpton, London. Pp. 236, illustrated with 25 engravings and a coloured plate. Price, 18s. net.

THE diabetic child should prove to be of more than usual interest to those working on the subject, not only because it provides them with pure diabetic lesions unaccompanied and uncomplicated by degenerative changes due to age, but also because it gives them a wider field in following up individual cases in the different periods of their lives. Herein lies the great value of Dr. Priscilla White's book, for not only has she made elaborate and exhaustive clinical studies based on over 700 cases, but also she has literally lived with her young diabetic patients, which gave her the unique opportunity of a very close and intimate study of individual cases, a thing not possible otherwise.

Dr. White's book deals with the whole subject exhaustively in all its aspects, physiological, pathological and practical, and should prove to be of great value to everyone working on the subject.

J. P. B.

VITAMINS AND OTHER DIETARY ESSENTIALS.—

By W. R. Aykroyd, M.D. London: William Heinemann (Medical Books), Ltd., 1933. Pp. 218. Price, 7s. 6d.

THIS book published at the price of the usual novel might well replace the next purchase of regular novel readers, for within its pages they will find entertainment combined with a great deal of sound information which is set out in such a way that it can be easily applied to the selection of food in any middle class home.

The first few chapters deal with general dietetic factors and are followed by seven chapters in which the various diseases due to vitamin deficiency are discussed, and several final chapters deal with diet on a broader basis. The book is clearly and simply written and the author has the power of trenchant criticism and epigrammatic phraseology which makes the reading of it a real pleasure. It can be taken up by any one who is wholly ignorant of the subject of dietetics and there is nothing in it such a person cannot understand. It is accordingly an excellent book for a beginner and it is a pity the author did not give a list of references of the authorities to which he refers and thereby enable the beginner to delve further into the subject. One of the most valuable characteristics of the book is that it has put vitamins back in their proper place in the dietary scheme, for when Professor Hopkins first used the term he defined vitamins as accessory food factors and many subsequent writers apparently forgot the word accessory and seemed to look on vitamins as the food itself. The author also tells where a supply of vitamins may be had in ordinary articles of diet instead of giving

the impression they are only obtainable in expensive special preparations.

It is a book which will be of value to medical men as well as to the lay public, by whom it may be read with complete understanding.

P. A. M.

THE SANITARY INSPECTOR'S HANDBOOK.—By

H. H. Clay, F.R.San.I., F.I.S.E. London: H. K. Lowis and Co., Ltd., 1933. Pp. xx plus 386, with 93 illustrations. Price, 15s.

WITHIN the compass of less than four hundred pages the author has written on all subjects with which a Sanitary Inspector has to deal in the discharge of his duties in various capacities in a country where the sanitary laws have made tremendous progress in all directions bearing on health. The book starts with the evolution of public health law; the outstanding events given in the chapter are well calculated to inculcate into a would-be sanitary inspector enthusiasm for the study while the full list of duties and the details of the training will form an admirable introduction to it. All the chapters which follow bear the stamp of the experience and acumen of the author; they are remarkably up-to-date, as a rule complete, and yet concise; the instructions cover all aspects of the subject, are eminently practical, and have been fittingly based on various sections of the corresponding Acts, Regulations and Orders. The following comments, however, may not be out of place:—

On page 121, line 3, while advising a reservoir of non-metallic material for storage of rain water, the attention of the reader might be drawn to the highly aerated and very soft character of the water and the consequent risk of a metal, like lead, being dissolved by it. In chlorinating water which is also filtered, as advised in the last two lines on page 136, will the quantity of chloride of lime added be the same as in the treatment of polluted water, viz, one part of free chlorine available per million of water? Under the heading of water softening, pp. 137–139, the base-exchange method has been described simply as an alternative to the softening by heating or by adding lime, but the special merit of the former lies in its ability to free the water both from temporary as well as permanent hardness while the latter can remove the temporary hardness only. On page 139, we read 'These possess the power of absorbing lime and magnesia salts, and replacing them with their equivalent of bicarbonates as, for example, bicarbonates of soda'; this line is misleading. It would be clearer to say that the process replaces calcium and magnesium salts with the equivalent of corresponding sodium salts, viz, carbonates of soda in the case of carbonates of calcium and magnesium, and sulphate of soda in the case of sulphate of calcium and magnesium.

Sampling water for bacteriological analysis is delicate work; not only should the sample bottle be a thoroughly sterilized one which after filling should be packed in ice, as advised on page 140, but every precaution should be taken against contaminating the water in any way during sampling it, for which there might be specific directions for the students. While the bottle for the sample for chemical analysis should be washed thoroughly with the same water before filling, as advised in the previous page, this will not only be unnecessary but undesirable with the sterilized bacteriological bottle. Line 30 on page 271 reads 'milk should be presumed not genuine if it contains not less than three per cent of milk fat' the second 'not' was evidently inserted in error.

The book will be greatly appreciated by students preparing for the sanitary inspectorship examination; it will undoubtedly be also very useful to sanitary inspectors serving in Great Britain. In India, the people mostly live in villages under widely different conditions; but in towns the problems of public health are similar to though not exactly the same as those in England, and our sanitary laws and by-laws are based as a rule on English laws and regulations, so the sanitary officers

working in cities and towns of this country will find in the book, a valuable guide in carrying out the details of their duties and in advising their local authorities regarding improvement of sanitation and public health of their towns.

B. B. B.

FOOD AND THE PRINCIPLES OF DIETETICS.—By R. Hutchison, M.D., F.R.C.P., and V. H. Mottram, M.A. Seventh Edition. London: Edward Arnold and Co., 1933. Pp. xvi plus 630. Illustrated. Price, 21s.

Dr. Hutchison's name as a keen physician and a gifted clinical teacher is too well known in medical circles to need any special introduction. His book on 'Food and the Principles of Dietetics' was first published in the year 1900, and for the last 32 years it has successfully maintained its position as a standard work of reference on the subject. Our ideas on dietetics have undergone very extensive changes during recent years particularly on account of the recognition and isolation of the vitamins. In order to keep pace with this increase of knowledge the author has collaborated with Professor Mottram, and their joint efforts are represented in the seventh edition. This edition has been extensively revised and reset. The first three chapters have been completely re-written through the help of Professor Mottram. The coloured plates showing the food values of the common articles of food are novel features and are especially instructive. The new edition, we are confident, will not only maintain its well-earned popularity, but will enhance the prestige of its predecessors.

R. N. C.

ANATOMY OF THE EYE AND ORBIT. INCLUDING THE CENTRAL CONNECTIONS, DEVELOPMENT, AND COMPARATIVE ANATOMY OF THE VISUAL APPARATUS.—By E. Wolff, M.B., B.S. (Lond.), F.R.C.S. (Eng.). London: H. K. Lewis and Co., Ltd., 1933. Pp. viii plus 310, with 173 illustrations. Price, 31s. 6d.

This book will naturally appeal only to the specialist whose interest in anatomy does not extend beyond the orbit and its contents. It is beautifully illustrated, most of the figures being original, and the book is printed on heavy art paper. It is altogether a pleasing production and is a credit to both author and publishers, and the reviewer's only regret is that he cannot recommend it to the general medical public. The reasons of this are, that although the price is high when one considers the limited scope of the book it is not too much if the form of presentation of the subject is the criterion of its value; but when the reader can acquire nearly all the information given in the volume together with the anatomy of all the rest of the body for the expenditure of only a little more money, this book must be classed as a luxury and not a necessity to the profession at large.

MODERN PHARMACOLOGY AND THERAPEUTIC GUIDE.—By Akhil Ranjan Majumder, M.B. Published by S. P. Majumder, Calcutta. Third Edition. Pp. viii plus 602. Price, Rs. 5. (Obtainable from the Book Company, Ltd., Calcutta.)

This book was first published in 1929 to provide a handy manual to the students going up for the licentiate standard of the State Medical Faculty examinations. That the book has served its purpose and is a certain answer to the expressed need of the students is more than evident from the rapidity with which two editions were consumed and a third edition called for. The science of therapeutics and pharmacology is fast progressing and a good many additions have naturally been made to keep the book up to date. Amongst the important additions may be mentioned the chapters on immune therapy, on preparations of invalid foods, on the calorific and vitamin values of various food-stuffs in common use in India, and on radiotherapy. In writing the last-named chapter, the author has obtained

the services of a radiologist and technician. The numerous prescriptions appended in the footnote are features which cannot be passed by without comment. The beginner will appreciate it thoroughly in view of the fact that difficulties are usually met with in writing out a good recipe.

The book, we have little doubt, will be of assistance to those who have to revise rapidly their knowledge of pharmacology and therapeutics in general. To the worried student whose final examinations are within sight, the book will be a sympathetic friend. It should not, however, be forgotten that it is a sort of a synopsis of the vast subject of pharmacology and therapeutics, and cannot replace a standard and authoritative textbook; any attempt to make it serve this purpose will inevitably lead to failure.

MELIODOSIS.—By A. T. Stanton, C.M.G., M.D., F.R.C.P., and William Fletcher, M.D., M.R.C.P. London: John Bale, Sons and Danielsson, Ltd., 1932. Pp. lv plus 59, with 37 plates.

This is No. 21 of the studies from the Institute for Medical Research, Federated Malay States, and deals with the very deadly and fortunately rare disease Melioidosis. It was first reported in the *Indian Medical Gazette* in 1912 by Whitmore and Krishnaswami and since then of the 83 recorded cases only two have recovered and a correct diagnosis has been made before death in only nine cases. That the clinical diagnosis of melioidosis is difficult is well illustrated by the different diagnoses such as cholera, typhoid fever, malaria, amoebic abscess of the lungs, and glands that have been made in Ceylon, The Malay States, Ceylon and the Dutch East Indies are the only countries where melioidosis is known to attack animals and although cases of human infection have been so far reported from Burma and the Malay States only, we agree with the authors when they state that it is highly improbable that melioidosis is limited to the few places where its presence has been detected. Its symptoms are so varied and obscure that it is seldom diagnosed until after death, and then only in those places where a bacteriological examination can be made. Even when laboratory facilities are available the disease may escape recognition by those who are unfamiliar with it, because the bacillus grows so profusely that it is apt to be mistaken for a contamination.

The authors have dealt exhaustively with the clinical, pathological and bacteriological aspects of the disease in which they have been interested for a number of years. The illustrations which make up more than half the volume are a remarkable feature of this well prepared book.

This account of melioidosis should be in the hands of everyone who practises in the tropics and it is very probable that it will lead to the recognition of melioidosis in many parts of the world. This book will prove invaluable in laboratories engaged in the investigation of tropical diseases.

C. L. P.

DISEASES OF THE EYE.—By Ernst Fuchs. The 15th German Edition as revised by Professor M. Salzmann. Translated into English by E. V. L. Brown, Professor of Ophthalmology, University of Chicago. This is the 10th Edition in English. It has 255 illustrations and 41 coloured plates. Philadelphia and London: J. B. Lippincott Company, 1933. Pp. xviii plus 641, with 255 illustrations in the text and 41 coloured figures. Available from Messrs. Butterworth and Co. (India), Ltd., Calcutta. Price, Rs. 31-8.

'Fuchs' Ophthalmology' has been a household word to ophthalmologists for over 44 years. Each succeeding edition got larger and larger, as is usual, till the last edition became altogether too unwieldy. The present volume has been reduced by some 350 pages by the omission of the Introduction and the chapters on Examination of the Eye, Refraction, and Operations,

as well as the special chapter on Refraction by Douane. These omissions in no way detract from the value of the book and these subjects are fully dealt with in other publications.

This new edition of Fuchs is still essentially like the old one and will still be read, consulted, and quoted as one of the best and most comprehensive textbooks in ophthalmology. The value of this edition has been greatly increased by the addition of forty-one coloured drawings of fundus conditions, both normal and abnormal. These drawings have been made by a man who is, at the same time, an artist and an ophthalmologist of international repute, to wit, Professor Salzmann and who is also responsible for the revision of the 15th German Edition from which this translation has been made. Unfortunately that edition was published as long ago as 1924, so that this translation is out of date as regards, for example, recent surgical treatment of detached retina, the newer filtration operations for glaucoma, and so on.

The translation itself leaves a very great deal to be desired.

The German construction has been too closely followed and one is conscious throughout the book of a phraseology which is quite un-English. Often the translation of a word is not only inaccurate but even misleading. For instance to quote only a few examples:—a rifle bullet is translated as an 'infantry charge'; squeezing of the lids becomes 'knifing of the lids'; 'tearing' is used for laceration. This has the merit of being a much shorter word but it has no other merit. Then again 'vessel free' and 'vessel rich' are used for vascular and avascular.

Perhaps however these are only Americanisms. At any rate the English spelling is Americanized throughout the book and this does not add to its attractiveness.

All these defects are only minor ones and the book remains one of the best and most comprehensive textbooks on ophthalmology.

I notice that the beautiful coloured plates at the end of the book are produced in Germany. I assume that is why it is possible to retail the book at the comparatively low price of Rs. 31-8.

H. S. C.

THE TREATMENT OF FUNCTIONAL NERVE CASES BY THE METHOD OF NEURO-INDUCTION.—

By Leonard Inkster, M.A. (Oxon.), M.R.C.S., etc. London: H. K. Lewis and Co., Ltd., 1933. Pp. vii plus 78. Price, 3s. 6d. net.

ALL books on psychotherapy are characterized by a dominant note of optimism with regard to the treatment of the various maladies which the 'flesh is heir to'. This book is no exception. Written in an easy-flowing and attractive style, the book enthusiastically stands for a method of neuro-induction which was originally enunciated by Dr. Heydn Brown. Neuro-induction is a form of treatment in which we aim at securing and keeping a state of absolute relaxation of mind and body. It is neither psychoanalysis nor hypnosis nor 'conscious suggestion' in the sense in which these terms are commonly used. It is a sure and even an easy method to practise. The technique is best explained in the words of the author:—'When, at the request of another, the patient lets the hand down and lowers the eyelids, relaxation occurs.'

By following this technique of neuro-induction the author reports very encouraging results in a large variety of cases. According to him, it brings ease of mind and body from the very beginning, and allows of a cumulatively increasing ease as the treatment continues. As an instance of the success of the method the author refers to cases of asthma where neuro-induction acts like adrenaline in relieving spasms and restoring normal tone to the arterioles.

The reviewer has not much experience in India of the method advocated and does not feel competent to give any opinion on the degree of success or failure of the method in the hands of expert psychotherapists.

It is however conceivable that a large measure of success will be obtained in cases where the mental factor is predominant.

R. N. C.

PHYSICAL CHEMISTRY FOR STUDENTS OF BIOLOGY AND MEDICINE.—By D. I. Hitchcock, Ph.D. London: Baillière, Tindall and Cox, 1932. Pp. xii plus 182, with 26 figures. Price, 15s. 6d.

A KNOWLEDGE of the rudiments of physical chemistry is essential to the proper understanding of the physiology of the human body; the subject is consequently an important part of any medical course. Physical chemistry is not usually a separate subject in the medical curriculum but the student is taught the necessary fundamentals of the subject in his chemistry and physiology courses. The writer of the book under review has collected into one volume twelve chapters on different physio-chemical subjects which are important to the medical student and essential to most medical research workers.

The subjects are dealt with concisely and in most cases clearly, but the author assumes a familiarity with chemical formulae and simple chemical reactions; this is justifiable but it does not make the book easy for the casual medical reader who has left chemistry behind him for some years. A useful feature of the book is the list of references; in each chapter not only is the reader referred to those authorities where he can read up the subject more fully but the special chapter of the books referred to is also indicated. It should prove a useful book to the medical student, and to the medical research worker who wishes to brush up this particular subject.

PITUITARY BODY AND HYPOTHALAMUS AND PARASYMPATHETIC NERVOUS SYSTEM.—By Harvey Cushing. London: Baillière, Tindall and Cox. Pp. viii plus 234, with 97 figures and 2 coloured plates. Price, 29s.

PROFESSOR HARVEY CUSHING is one of those international figures who have contributed materially to our knowledge of the pituitary body. In this book, an attempt has been made to collect some of his important lectures relating to the pituitary body, hypothalamus and the parasympathetic nervous system. The reader will find in these lectures a veritable mine of information regarding the physiology and pathology of the pituitary region of the brain, and the specialist will find a detailed and expert discussion of all those practical and theoretical problems of diagnosis and treatment which render tumours of the pituitary gland a difficult medical speciality. The richness of material available, the freedom with which the subject is presented and the elaborate discussions and analyses with which the central questions at issue are pursued, are features which mark the book as being above the average. Photographs and coloured plates which are well chosen and very suggestive are to be found in profusion. The get-up is excellent and leaves nothing to be desired. All those who are interested in pituitary surgery are advised to obtain a copy of the book.

R. N. C.

A TREATISE ON MATERIA MEDICA AND THERAPEUTICS.—By The late Rakhaldas Ghosh. (Thirteenth Edition by B. N. Ghosh, F.R.F.P. & S.) Calcutta: Hilton and Co. Pp. xv plus 712. Price, Rs. 7-8.

'MATERIA MEDICA and Therapeutics' by Dr. R. Ghosh first saw the light of day in the year 1901 and during the 32 years that have elapsed since then it has passed through thirteen editions. The twelfth edition had to be reprinted to meet the demands of medical students. This fact alone is a measure of the immense popularity of the book and shows in no unmistakable terms the useful purpose it is serving amongst the student

community. For many years, junior students in Indian medical schools and colleges have looked upon it as the standard book on the subject.

The system of teaching therapeutics followed in the early years of the twentieth century has undergone radical changes. Physiology and pharmacology are now considered to be the basis of treatment and pharmacology is now included in the medical curriculum to provide a scientific basis for the study of therapeutics. Any recent book on therapeutics which does not provide a groundwork of the broad pharmacological principles will therefore fail in its chief purpose. It is a pleasure to note that the author has not ignored the modern developments of pharmacology and has recast the book thoroughly in the light of modern teachings.

The publication of the new British Pharmacopœia, 1932, has necessitated many changes in that section of the book which deals with materia medica proper. Recent advances have also occurred in our knowledge regarding endocrines and vitamins and the author has not spared any pains in incorporating all the recent teachings in the present edition. A chapter on radiation therapy has been added and this will be of special value in view of the increasing attention that is manifest in the direction of treatment by means of radium and ultra-violet emanations. The chapter on Indian indigenous drugs is also worth special mention. It is high time that Indian students should learn the useful drugs that are available in their own country and can be used as cheap substitutes for the more expensive official preparations.

In a book of this nature typographical errors are very difficult to avoid and the reader will find a number of them. In the chapter on opium and morphine the author has remarked on the utility of narcotine in malaria. Though this was mentioned by the Royal Commission on Opium nearly thirty years ago, recent work has definitely disproved the statement.

Two of the most important discoveries in the realm of endocrinology are perhaps those concerning the manner in which the anterior pituitary gland controls reproduction and the action of vitamin A in maintaining resistance against infection. These matters have not received

proper attention. It is however hoped that these will be rectified in future editions.

R. N. C.

NATURAL CHILDBIRTH.—By G. Dick Read, M.D. (Cambridge). London: William Heinemann (Medical Books), Ltd., 1933. Pp. ix plus 127. Price, 7s. 6d.

DR. GRANTLY DICK READ has written a fascinating book, which will do much to achieve his ambition to 'initiate such change as will in future generations re-establish childbirth in the civilized races as a painless procedure'.

He does not accept the teaching that parturition must of necessity be a painful procedure; he does not believe that the modern woman is becoming more and more mechanically inefficient for a function on which the whole future of the race depends, and he has endeavoured in the book to fathom the problem of pain and its elimination during childbirth. It is a problem which every woman and all but the dullest men ponder over at some time, and Dr. Read's book opens up a very fruitful approach towards its solution.

His conclusion is that the instincts and accompanying emotions govern the type of labour. Fear in the modern civilized woman is often stronger than the emotions associated with the reproductive and parental instincts, and instead of the harmonious working of the reproductive organs and an easy birth under the strong stimulus of pleasing emotions, there is disquietude and even terror reflected in disharmonious working, impaired function, and a difficult birth.

Dr. Read has much sound advice to give to doctor and nurse alike on the preparation of the patient and the conduct of the confinement, and no practitioner who aspires to a reputation as a successful obstetrician and whose ambition is to leave each patient functionally perfect in her plural rôle of woman, wife and mother, can afford to neglect to read this book. It will give him a new viewpoint on childbirth, a deeper understanding of the woman in pregnancy and labour and will enable him to acquire that 'personality' which makes for success and which is too often thought to be the monopoly of those blessed by the gods.

Annual Reports

ALL-INDIA LEPROSY CONFERENCE

THIS conference convened by the British Empire Leprosy Relief Association was held at the All-India Institute of Hygiene and Public Health from the 27th to the 29th of March last. Twenty delegates attended, and a large amount of work was got through and several important papers dealing with the many aspects of the leprosy problem were read. Unfortunately lack of space prevents us giving abstracts of these papers, but we give below the resolutions and recommendations of the conference, which give a good idea of the extent of its activities.

RESOLUTIONS

Resolution I. Co-ordination and Organization.

In view of the wide prevalence, severity and infectiousness of leprosy in India it is resolved:

(a) That there is a great need for consolidation, co-ordination and extension of anti-leprosy work.

(b) That as leprosy is essentially a public health problem, every effort should be made to make anti-leprosy work an integral part of the public health system, using the latter term in its widest sense, i.e., in both its curative and preventive aspects.

(c) That it is desirable that in every province or state there should be a specially trained leprosy officer.

(d) That for the more efficient working of anti-leprosy measures a provincial or state leprosy board be formed in each province or state. This board should be chosen from representatives of the Medical and Health Departments, Mission to Lepers, British Empire Leprosy Relief Association and any other agency interested or engaged in leprosy work. The provincial leprosy officer should work in close collaboration with this board of which he may with advantage be a member. The functions of this board would be to co-ordinate all present and future anti-leprosy measures throughout the province.

(e) That similarly in each administrative district where leprosy is highly endemic there should be a special leprosy officer, who should work in close collaboration with the special leprosy officer of the province.

(f) That in such districts a district leprosy board should be constituted, consisting of the heads of the medical and health departments, and of any local leprosy organization, together with the senior government officials, representatives of the district board and of the public. The functions of this board will be to co-ordinate all anti-leprosy measures in the district. The local leprosy officer should work in close collaboration with this board.

Suggestion.

It is suggested—

(a) That the provincial or state leprosy board be convened by the Surgeon-General or the Inspector-General of Civil Hospitals in consultation with the Director of Public Health.

(b) That the district leprosy board be convened by the district magistrate in consultation with responsible district officers, medical and administrative.

Resolution II. Training

Because of great difficulties connected with anti-leprosy work (e.g., detection of early cases, treatment and prevention) it is resolved:

(a) That instruction in leprosy by a specially trained doctor should be included in the curriculum of all medical schools and colleges.

(b) That special courses should be given at convenient centres where clinical material is available to all government doctors. Private practitioners should be encouraged to attend these courses.

(c) That a more thorough training should be given in a suitable institution to district health officers and medical men engaged in special leprosy work. This course should be of at least a fortnight's duration.

(d) That all dispensers, employed by Government or local bodies, should be given a short course of training in leprosy; such a course should include practical instruction in the technique of injections.

(e) That sanitary inspectors should be trained so that they can recognize leprosy, and be able to aid in propaganda and survey work in the villages. This work should be done under the supervision of the district health officer in co-operation with the special leprosy officer where such exists.

(f) That other workers, such as sanitary or health visitors, public vaccinators, dais, etc., should be trained to recognize leprosy; local leprosy institutions might be used for this training.

(g) That all medical officers and others connected with the recruitment of industrial labour should be trained to recognize leprosy; and that all labourers should be examined for leprosy before recruitment and periodically afterwards.

Resolution III. Special Leprosy Clinics

The need for forming and maintaining an adequate standard of anti-leprosy work in rural areas is recognized. It is therefore resolved:

(a) That there should be in each administrative district where leprosy is highly endemic at least one model clinic under a whole-time leprosy officer. This clinic would act as a demonstration of the best methods of carrying out an anti-leprosy campaign; it would also act as a centre for prevention, and for the training of doctors and layworkers in the district and thus eventually lead to the establishment of other anti-leprosy centres.

(b) That a memorandum be prepared describing the functions and scope of the work of a model clinic and made available for distribution to all district officers, to medical, administrative and local bodies, and to those interested in the leprosy problem.

Resolution IV. Leprosy Clinics in General Hospitals

It is recognized that leprosy can be better treated in clinics especially devoted to that purpose, but in view of the large number of cases needing treatment, it is resolved that all government medical officers and local practitioners should be encouraged to treat leprosy and initiate anti-leprosy schemes along similar lines to those in the model clinics.

Resolution V. In-patient Institutions

Although emphasis is laid on the need for leprosy clinics to carry out treatment and prevention, the need for residential institutions has not diminished but rather increased. These institutions provide for the voluntary isolation of infectious patients and for the treatment

of cases the nature of which demands hospital care. It is therefore resolved:

(a) That the formation of voluntary isolation colonies be encouraged wherever possible.

(b) That the accommodation in the existing institutions be used to a greater extent for the isolation of infectious cases.

(c) That it is desirable that there should be, where possible, closer co-ordination between leprosy clinics and leprosy institutions.

Resolution VI. Research

It is recognized that highly specialized research is best done in efficiently equipped laboratories; but in order that other branches of research may be facilitated it is resolved:

(a) That more use should be made of the facilities in existing institutions and that the staffs of these institutions should be encouraged to undertake such work.

(b) That there is a need for the establishment of a special leprosy investigation centre in a suitable rural area in order to make an intensive study, over a prolonged period, into the epidemiology and control of leprosy.

Suggestion.

It is suggested that the British Empire Leprosy Relief Association might make arrangements for leprosy workers in the provinces to obtain any necessary literature bearing upon any particular aspect of the problem which they are studying.

Resolution VII. Leprosy in Children

Available statistics show that in endemic areas the incidence of leprosy in school children varies from 0.5 to 3 per cent. This conference is of the opinion that in such areas all school children should be examined for leprosy. Treatment should be provided for all definite cases found, and isolation of all infectious cases strongly urged.

RECOMMENDATIONS

(1) It is the opinion of the conference that in leprosy *general treatment* is of paramount importance. While there are many forms of *special treatment*, experience has shown that of the methods at present available the following are the most effective and practicable:—

Injections of hydnocarpus oil or esters with 4 per cent creosote, which may be given intramuscularly, subcutaneously or intradermally.

Since the intradermal method of injection requires more skill and time than the other two methods, its use should be chiefly confined to in-patients; it can however be used in out-patient clinics in suitable cases, provided sufficient time and skill are available; otherwise in out-patient clinics intramuscular and subcutaneous infiltration should be used.

(2) Whatever method of injection is used, the effects can be intensified by local application of trichloroacetic acid solution.

(3) An opinion has frequently been asked regarding the relative value of hydnocarpus oil and esters in the treatment of leprosy. While the esters have been declared by many workers to be the more effective of the two, the opinion of this conference is that the oil is almost if not quite as effective as the esters. It has the advantages of being cheaper and uniformly less irritant, while the disadvantage of its greater viscosity can be overcome by heating it sufficiently before injection. Any possible advantages of esters may be counter-balanced by the possibility of treating larger numbers of patients by the cheaper drug.

(4) While many patients can be treated effectively as out-patients, there are others who, because of complicating conditions, cannot improve without careful examination and treatment in hospital. It is therefore important that there should be beds where such patients may be kept temporarily under observation and treatment.

Captain H. W. Mulligan, Assistant Director, Malaria Survey of India, on foreign service under the Indian Research Fund Association, is granted leave for 1 month, with effect from the 1st September, 1933, or subsequent date from which he may avail himself of the leave. His services are replaced at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

PROMOTIONS

Colonel to be Major-General

H. R. Nutt, V.H.S. Dated 20th July, 1933.

The provisional promotion to the rank of Major of the undermentioned officers is confirmed:—

D. P. Bhargava.

B. R. Tandon.

Lieutenant to be Captain

W. Fleming. Dated 22nd May, 1933.

Note

LIVOGEN

DESCRIPTION

LIVOGEN is a highly concentrated liquid preparation containing in one fluid ounce the whole of the hæmatopoietic principles (including vitamin B) of four ounces of fresh liver. It contains additional vitamin B extract equivalent to one ounce of fresh yeast in each fluid ounce, together with five grains of hæmoglobin for the supply of iron in readily-assimilable form.

It will be observed, therefore, that livogen contains the two essential factors for normal blood formation—namely, liver extract and organic iron. For those particular cases of specific anæmias in which massive doses of iron are indicated iron ammonium citrate may be dispensed with livogen, the two products being in every way compatible.

Regarding the 'B' vitamins in livogen it is interesting to observe that results of recent scientific research have demonstrated that this complex also plays an important part in the process of regeneration of impoverished blood, and, in addition, it maintains appetite, promotes the proper action of the digestive tract including peristalsis, and sustains normal healthy growth. Thus the therapeutic value of livogen for the promotion of blood regeneration in all conditions of lowered vitality can be properly appraised by a study of its composition which is based upon the latest findings of research on the treatment of the various conditions arising from blood degeneracy.

USES

The principal uses for livogen in the ordinary course of everyday medical practice are in the treatment of the many conditions of weakness and lowered vitality of which a bad blood picture is a symptom. Examples of such conditions are those which accompany acute disease, the malaise following severe illness, weakness following a surgical operation and the form of depression which is so characteristic of influenza convalescence. Livogen is of value also as a general tonic in the many similar, but milder, conditions of lowered vitality, debility and lethargy which are met with almost daily in clinical practice; in such conditions the ingestion of livogen produces not only a reconstructive tonic effect upon the blood, but, by stimulating the appetite, it

renews vitality and hastens the return to normal health.

Livogen administration is remarkably beneficial also in cases of specific anæmias—both primary and secondary. In reporting on its value in these cases a physician in charge of an important hospital states that 'the severe secondary anæmias of various ætiologies.... respond exceptionally well to livogen exhibition.... it is quite the best treatment.... the effect is astonishing'.

Furthermore, in pregnancy and lactation, in febrile conditions and as a blood regenerator after severe hæmorrhage, livogen is of distinct value.

ADMINISTRATION AND DOSAGE

Livogen is highly palatable; it may be sipped neat from a wine glass, or taken in water, soda-water, or other suitable vehicle, preferably after food. It causes no gastric reaction, and it is acceptable to the most fastidious.

The dose varies from two teaspoonfuls to two tablespoonfuls per day according to the needs of the case, the average dose for an ordinary case of general debility and lowered vitality following illness being two teaspoonfuls once or twice daily.

It is a product of The British Drug Houses Limited, London.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

CARDIOVASCULAR AND OTHER MANIFESTATIONS OF EPIDEMIC DROPSY

By R. N. CHOPRA, M.A., M.D. (Cantab.)
LIEUTENANT-COLONEL, I.M.S.

and

S. C. BOSE, M.B. (Cantab.), M.R.C.P., D.T.M. (Lond.)

(From the School of Tropical Medicine, Calcutta)

WITHIN recent years epidemic dropsy has affected a large section of the population of the province of Bengal; its troublesome clinical manifestations and a fairly high mortality rate have attracted considerable attention, and much research has been carried out on this disease. The senior author (R. N. C.) during the last nine years has studied a number of epidemics in Calcutta. The majority of patients suffering from this condition, who came to the School of Tropical Medicine, Calcutta, for treatment, were admitted under his care into the Carmichael Hospital for Tropical Diseases and carefully studied. Thorough clinical examinations were made and the aetiological, pathological, bacteriological and biochemical implications were carefully investigated. The results of some of these observations have already been published. In this paper we propose to describe briefly the results of the studies of the patients who came under our observation during the latter half of last year. One of us (S. C. B.), who has extensive experience of cardiology in the tropics, studied these patients with regard to their cardiovascular changes. Any remarkable features in connection with this syndrome, which have come to our notice during these studies, have also been included in this paper. It is worthy of note that many striking features seen in the patients were typical of those occurring in acute specific infectious diseases such as measles, diphtheria, enteric fevers, etc., thus lending additional support to the views already expressed regarding its infective nature.

(i) *Incidence.*—It has been observed by previous workers that this syndrome shows a peculiar periodicity. In certain years, a widespread epidemic is met with, followed by a quiet period. These waves of morbidity are difficult to explain. This year, the seasonal rainfall has been excessive and the humidity has been abnormally high. The mean temperature has been more or less the same as in other years, and the method of storage of rice has not altered in any way, yet there have been hardly any admissions into the hospital and very few persons with this disease have come to the outpatient department even from Howrah, the notorious plague-spot from where most of the

Calcutta epidemics start. Some of the members of the staff of this institution, who were affected some years ago, and generally feel off-colour directly the season arrives, have had no recrudescence of unpleasant symptoms of their old malady. Each epidemic brings forth its own peculiarities and cases of one year greatly differ in severity, signs and symptoms from those of another year. The morbidity rate as well as the incidence of mortality vary enormously. In some epidemics the death rate is very high while in others it is exceedingly low. The epidemic of 1932 referred to in this paper was one of moderate severity, with a low mortality.

(ii) *Selection.*—Although all the members of a family are on exactly the same diet, the severity of symptoms varies enormously in different individuals. Children under five and persons over fifty either escape entirely or are only very slightly affected. This raises the question whether for each person there is a certain critical or absolute quantity of the noxious food-stuff ingested, beyond which symptoms arise, or perhaps the quantity of the noxious material is relative to the other articles of diet consumed. Very young children usually consume small amounts of the affected rice in comparison with milk, and we have not seen many patients under five years of age.

In a previous paper, Chopra and Basu (1930) found the maximum age incidence to be between twelve and seventeen years of age and that nearly all the patients were under thirty. The young adult belonging to this group usually consumes the largest quantity of rice, both absolutely and relatively in proportion to other food-stuffs. Old persons, however, eat less, and often have but one rice meal in 24 hours, so that the critical quantity is probably not reached, and they escape. Further, pre-existing diseased conditions of the gastro-intestinal tract such as amœbiasis, hepatitis of amœbic or malarial origin, bacterial and parasitic infections of the bowels and other conditions which lower vitality, increase the susceptibility of exposed persons. In our present series of cases such infections occurred in almost every patient. To ensure rational and successful therapy of these patients a thorough clinical examination is necessary.

(iii) *Clinical types.*—While cardiac involvement is the rule, its severity is not uniform. In certain epidemics, severe diarrhoea is the predominant symptom and the cardiovascular symptoms are of a mild nature. In patients with constipation, the cardiac features usually progress rapidly and become serious, often leading to a fatal end. In yet another group, mild cardiovascular symptoms are associated with a high rate of ocular complications such as glaucoma; there is as a rule only slight diarrhoea and œdema of the legs in these patients. Our belief that diarrhoea is produced by the toxic bases in the intestines which not only damage the capillaries and

produce œdema, but also produce exfoliation of the mucous lining of the gut, is further strengthened by the study of this series. The patients with advanced cardiac failure during the epidemic under review all recovered, except two, one a very old infirm and fat woman admitted *in extremis*, and the other a hopelessly anæmic girl of eighteen.

(iv) *Ætiology*.—The study of this epidemic and the series of cases discussed in this paper has further strengthened the views expressed by the senior author (Acton and Chopra, 1925) that epidemic dropsy and beriberi belong to a toxic group, where the three main signs are œdema, hypertrophy followed by dilatation of the heart, and peripheral neuritis. In epidemic dropsy usually only two of these signs are present, i.e., the œdema and the effects on the heart, and in dry beriberi there are cardiac lesions, marked peripheral neuritis, but little or no œdema.

This syndrome is produced by certain poisons elaborated in food which is improperly stored. Beriberi has been produced by rice or by the exclusive use of tinned provisions, and living on a diet mainly consisting of dried fish is said to have produced an epidemic in Labrador. It is well known that, provided proteins or amino-acids are present, the decomposition of these substances to toxic products is not the exclusive property of any particular protein or any particular species of bacterium. All cases of epidemic dropsy seen by us occurred among those whose main dietary consisted of rice and in almost every case it was established that the rice was diseased. A spore-forming proteolytic bacillus of the *vulgatus* group is commonly found in the diseased grain (see table of cases). In this connection it may be mentioned that Bernard of Saigon found a very similar bacillus and described an infection occurring in animals when fed on these bacilli. We have further confirmed our previously enunciated views that there is no close connection between avitaminosis and this disease, because if this were the case it would occur in an epidemic form when associated with famine conditions and this certainly has not been so in Bengal. The findings of Acton and Chopra (1927) regarding this bacillus occurring in the urine and stools of patients were confirmed in a number of other cases. Toxins elaborated by this organism resemble histamine in having a powerful effect on the capillaries.

Physical signs and subjective symptoms

Dyspnœa.—This is an early feature, complained of before gross evidence of cardiac damage appears (see table of cases). At first it is a quick and shallow hyperpnœa of the type seen in some anæmic states. It is either mild and constant, or spasmodic, often being worse at night. As the mechanism is obscure, the following discussion

may be of interest. This primary hyperpnœa may be explained entirely by local lesions, i.e., by the turgid capillaries encroaching on the alveolar spaces and diminishing the calibre of the terminal bronchioles. Next we suspect some anæmia of the respiratory centre caused by the 'capillary crisis' elsewhere; the resulting anoxæmia would stimulate the centre to increased respiratory movements. Finally, cardiac failure with congestion supervenes and a CO₂ excess is added on to the oxygen-want. The patient with orthopnœa is not cyanotic but has an ashy pallor, called pallid asphyxia, which is almost a terminal feature.

Edema.—This occurs to a greater or lesser extent in all cases (see table). The condition, as met with clinically in anæmic states and in cardio-renal disease, is characterized by excess of fluid in the subcutaneous tissue spaces and is recognized by the affected part being pale, painless and pitting on pressure. We now know that two other conditions coexist with subcutaneous œdema and even ante-date its appearance, namely, general hydræmia and some excess of fluid in the tissue spaces of the skeletal muscles also. The existence of these two states is suggested by an increase in weight of the patient, and clinically obvious œdema can be predicted to occur after a few days of the above finding. The initial œdema of epidemic dropsy is quite distinctive in that it is of the solid type, and the affected skin is dusky-red, hot and tender on pressure, and it affects the skeletal muscles, heart and possibly the viscera. This swelling consists of two components, a small amount of transudate and a network of turgid capillaries. The hot flush is similar to an erythema, but differs in its darker colour, presumably on account of a poorer oxygen-content caused by stasis. Curiously, the stasis never reaches the degree to produce a cyanotic hue. With advanced cardiac failure, the œdema increases in amount and the skin pits more readily on pressure. It would be interesting to record the lower-limb volume in the various stages of the disease, whichever way it may terminate and to compare these figures with the total body-weight on the same dates.

The patient complains that his legs no longer carry him, but that he has to carry his legs after him.

The typical initial œdema is not strictly confined to the legs but may extend up to the root of the neck. The skin in facial or ocular œdema, however, is never of the red, hot type; but it is pale.

Anæmia is a prominent feature in all cases. Leaving aside other coexisting causes, such as parasitic anæmia, its degree is proportionate to the rate at which the malady progresses and to the more advanced degree of cardiovascular damage and heart failure. Even within the first

two or three days of the onset in most cases, a marked pallor of the face and mucous membranes is very distinctly noted. Other observers have found a moderate degree of hydræmia coexisting with œdema, as evidenced by a low specific gravity of the blood, and a low ratio of corpuscles to plasma. This hydræmic type of anæmia is revealed by a low hæmoglobin value with an erythrocyte count not lower than 3 or $3\frac{1}{2}$ millions per c.mm. Later in the disease, the anæmia may perhaps be explained by capillary hæmorrhages or by inhibition of the erythrocyte production due to the deleterious action on the hæmatopoietic system by the toxins absorbed from the gut. The main reason of facial pallor and anæmia in the early stages is probably the widespread capillary dilatation which produces capillary stasis all over the body and particularly in its lower half. This necessarily curtails the amount of blood in actual and active circulation. The arterioles and venules which lie above the level of the base of the heart are poorly filled and so pallor thereby results. Clinically, the anæmia seems more severe than the count of red blood corpuscles and the hæmoglobin value show.

Blood pressure.—Though in our previous paper the occurrence of high systolic readings has been noted, the unanimous finding in all well-established cases is a low systolic reading, rarely exceeding 110 mm. and a very low diastolic pressure of 50 mm. of mercury or less (see table of cases). This low mean blood pressure is fully in accord with the widespread capillary dilatation throughout the body.

Cardiovascular system.—When the invasion of a malady is heralded by prominent cardiac symptoms and signs, which rapidly get worse and often lead to a fatal issue, it is natural to concentrate on the myocardium as the seat of damage. One recalls the cardiac crises in diphtheria and enteric fever and expects to find in epidemic dropsy similar histological changes to those found in the above two diseases. But to one's disappointment the heart muscle, in even the worst cases of epidemic dropsy, shows neither inflammation, degeneration nor hypertrophy. Acton and Chopra (1927) were the first to study the histology of an epidemic dropsy heart. They described the increased vascularity of the myocardium, so that the smallest capillaries were readily seen. Besides the increased vascularity, œdema had separated the muscle fibres which themselves showed no changes. Later Shanks and De (1931) confirmed these findings, and found that the only remarkable change was a wide network of dilated capillaries separating the individual muscle fibres. It appeared as if the muscle fibres were being pressed upon from all sides by the dilated capillaries. These changes were uniformly spread throughout the right and left ventricles and there were no indications that the capillaries were more numerous or more densely packed in

the left ventricle than in the right. From these data no evidence can be adduced in favour of the popular conception of epidemic dropsy being a condition due to left-heart failure as contrasted with beriberi which is considered as a condition produced by right-heart failure. Further, Sir Thomas Lewis and other cardiologists do not endorse the old conception of dividing heart failure into two separate types, i.e., those due to left-heart and right-heart failure, respectively. The conception at present accepted is the division of heart failure, very broadly, into two types, namely, failure with venous congestion, and failure with anginal pain. It would therefore be reasonable to regard the heart failure in epidemic dropsy as being that of the congestive type.

The essential histological changes seen in the whole of the cardiovascular system are a very widespread capillary dilatation and stasis throughout the body but most marked in the dependent parts. Similar histological changes are seen in the epicardium and in between the muscle fibres of the myocardium throughout the ventricles and the auricles. There is no evidence of a cellular infiltration or proliferation around the capillaries or elsewhere. The muscle fibres, so far as can be made out, are perfectly normal in appearance. The toxins apparently have a special affinity for the capillary endothelium which they damage leaving the other cells untouched. It is therefore permissible to pause and consider if our previous conception of an essential primary cardiac failure should not be modified, and whether this widespread capillary dilatation and stasis of the whole circulation may not play the leading rôle in the onset and progress of cardiac failure. In short the true cause would appear to be an all-round circulatory failure accentuated by myocardial weakness and not a primary cardiac failure. It is well known that capillary dilatation with stasis beyond a certain degree will accommodate such an enormous quantity of blood that the big veins, the chambers of the heart and the larger arteries will become half empty, and circulation will be brought nearly to a standstill. In cases of advanced aortic regurgitation the arteries and dilated arterioles are poorly filled and therefore patients suffering from aortic disease tend to show pallor. Further, the heart failure in aortic regurgitation is rapidly progressive and ends fatally without much evidence of back pressure, venous stasis and congestion of the systemic veins. Cyanosis is exceptional even towards the end, in cases of advanced aortic regurgitation. According to Lewis, in all cases of advanced aortic regurgitation, there coexists a well-marked dilatation of the smaller arterioles and capillaries and it is the latter event which produces the typical Corrigan's or water-hammer pulse with a very low diastolic pressure. On account of the free leakage through the aortic valves, a large volume of the blood permanently

stagnates in the capacious distended left ventricle, which however takes no part in the active circulation. The associated dilatation of the arterioles locks up some more blood.

In the fulminating type of heart failure in epidemic dropsy the clinical picture is very similar to the above, and such signs and symptoms as well-marked suprasternal pulsation, pulsating carotids, a water-hammer pulse of low tension and a low diastolic pressure are present. In acute epidemic dropsy therefore we may conceive of a similar mechanism whereby the patient bleeds into his own distal capillaries; large quantities of blood thus stagnate in the capillaries and are cut off from taking part in the circulation. The contractile power of the left ventricle is too poor to drive the increased volume of the stagnant capillary blood to the veins and back to the right heart. Consequently the heart as a whole is badly filled and badly emptied. The coronary circulation depends for its integrity on an adequate systolic output from the left ventricle and a relatively high 'head of pressure' beyond the aorta. Both these factors thus suffer in epidemic dropsy and a certain amount of coronary starvation is rendered probable.

From our clinical experience in epidemic dropsy we would classify the diseased hearts into three well-marked clinical types:—

- (a) Acute, or fulminating: here the patient has the heart affected at the very start, failure progresses and death may occur within four to seven days. These cases resemble the picture of an acute left-heart failure. This type, with a high mortality, was common in the epidemics of 1926 and 1927.
- (b) Subacute or chronic: here the heart is less rapidly affected, and failure, from which recovery is usual, is a slow process. These cases resemble the picture of a combined right- and left-sided failure, with slight cyanosis, jugular distension and general systemic venous congestion. Our present series of cases fell under this group.
- (c) *Formes frustes*: here the heart either wholly escapes, or is very slightly affected. This type was seen in one previous year.

The existence of these three distinct types cannot be explained in terms of the varying degrees of histological changes in the heart wall itself. But it is easy to understand the mechanism of these three modes of cardiac failure, by recalling the picture of a general capillary dilatation. The degree and severity of circulatory failure along with a secondary cardiac weakness is directly proportionate to the degree and extent of capillary dilatation that exists. The acute fulminating type of failure starts with a very deep and extensive capillary

distension and stasis, somewhat similar to that in surgical shock or acute histamine poisoning. The blood is locked up in the capillaries, and thus is side-tracked from the circulation. Consequently the veins, the heart and big arteries are relatively empty, and sudden syncope and death may result. When the supply of fuel is cut off, the engine cannot continue its work. Clinically, these cases die neither showing cyanosis, jugular distension, a passively congested liver nor any distal œdema of passive congestion. Next, in the subacute or chronic type, a lesser degree and extent of capillary distension occurs and the veins and the right heart are better filled. Some venous stasis in the systemic circulation and right heart is obvious. In general, the more delayed the onset and the progress of failure, the more likely is the clinical picture to resemble a typical right-sided failure, and this is what we find in all our present series of cases. We are able to show a new orientation in our conception of the mechanism of the cardiac failure if we merely recall the essential morbid histology. What was previously called an acute left-heart failure is probably a condition of over-filled and multiplied capillaries, with a relative emptiness of the big veins of the right or left heart, a starved coronary circulation and half-empty large arteries. What was formerly called a right-sided failure, and which we do find in the more chronic types, is probably a condition of moderate capillary engorgement, an over-filled venous system and right heart, with comparatively less blood in the left heart and arteries.

We have briefly described the mechanism and the mode of progress of the cardiovascular disturbances in epidemic dropsy, which consist of cardiac failure of the congestive type aggravated by vascular disturbances in the peripheral circulation. The process of clear thinking is very materially assisted by the use of exact terms and we suggest that the typical damage and defects may be expressed as a 'cardio-capillary crisis'. Cardiac failure has been very tersely defined by Lewis thus: 'It signifies inability of the heart to discharge its contents adequately; and this failure culminates in manifestations with which we are all familiar, namely dilatation of the heart, general venous congestion and dropsy'. The 'capillary crisis' consists of an absolute lack of tone and resiliency of the distended walls of the capillaries whereby the blood, instead of being further propelled along to the venous system, stagnates and behaves as a useless but harmful dead weight to the process of circulation. As the cardiac failure progresses, the increasing dilatation of the right heart is reflected on to the big veins and then to their finer tributaries. As the left heart dilates and mitral incompetence and regurgitation eventuate, there is a relative emptiness of the aorta and of the whole arterial tree. To sum up the events in chronological order,

we start with the initial toxic capillary dilatation followed by cardiac failure, arterial emptiness and venous fullness. In left-sided cardiac failure, the aorta and arterial tree are but poorly filled; this results in oligæmia of the whole arterial tree and a relative starvation of the coronary circulation to the myocardium itself. In the acute fulminating type, this arterial emptiness is incompatible with life, there is no time for evidence of right-heart failure to appear, nor is there sufficient blood left over by the dilated capillaries to over-fill the venous system. In the more chronic types, however, the clinical picture is that of a typical back-pressure type of heart failure superimposed on the initial 'capillary crisis'.

Heart

Physical signs.—For the benefit of those who are not likely to meet with this condition in their practice, we would like to point out that, in the whole range of clinical medicine, we know of no other acute specific febrile malady where a perfectly strong and healthy lad or a young adult may be struck down within two or three days, with the fully-developed picture of an acute congestive type of cardiac failure. There is no other disease where, so early, the full fury of the onslaught is concentrated on the entire cardio-capillary system. In extreme cases, the acutely progressive congestive failure resembles the left-heart failure that is seen in the terminal stages of syphilitic heart disease with aortic regurgitation. And yet, post mortem, there is hardly any naked-eye or conspicuous histological change in the pericardium, myocardium or endocardium. In the milder intoxications, the heart failure resembles that in grave myocarditis. In children who remain alive for more than 4 to 6 weeks, the type of failure closely resembles that seen in mitral affections of rheumatic origin. True muscular hypertrophy, however, has not been met with in the few cases on which post-mortem examinations have been done, nor has any valvular or mural endocarditis been found.

In describing the clinical features we propose to adopt the classical scheme of Sir Thomas Lewis, namely, congestion, enlargement, valves, rhythm, infections, ætiology and vessels.

Congestion.—The typical signs are, marked fullness and pulsation of the jugular veins, enlarged and possibly pulsating liver, œdema of the legs, some general anasarca, and even ascites and hydrothorax. In the very acute cases, however, the systemic veins are not markedly engorged, only the lungs showing very early passive congestion and œdema. There is neither muscular hypertrophy nor any valve disease. This congestive failure furnishes yet another proof of the hollowness of the traditional theory of 'broken compensation' as the cause of a failing heart. Cyanosis is rare, except in those patients with a terminal broncho-pneumonia.

The initial pallor of the face and lips may progress to a pallid asphyxia, which is an ominous sign.

Enlargement.—The apex is usually displaced downwards and outwards, often in the 6th interspace beyond the anterior axillary line. The cardiac impulse is diffuse and wavy, as in the over-acting heart of dilatation. The left border is palpable outside the nipple. The upper margin of cardiac dullness reaches up to the 2nd costal cartilage, and a small patch of dullness is noted over the 2nd left costal cartilage and interspace near the edge of the sternum. Beneath this patch of dullness, distinct pulsation may be seen and felt, and on orthodiagraphy this appears to be the dilated pulmonary artery.

Valves.—These are never diseased. Abnormal cardiac sounds and bruits are heard and though they have lost their former pride of place, in modern heart work they have at least an academic interest. The first sound is short, sharp, toneless, and resembles so nearly the second sound that, with tachycardia, the heart sounds are almost 'tie-tie'. The most important organic bruit is that heard over the apex, systolic in time, conducted to the axilla and which partly or wholly replaces a weak first sound. Tradition holds this to be caused by a leak of the mitral valve and we regard it as such, since the heart is enormously dilated and a slack mitral ring is probable. But we wish to stress the importance of another systolic bruit that is heard over the pulmonary area, which has hitherto been neglected as being merely a hæmic or a functional affair. If one must consider bruits at all, a place of honour must be found for this probably pulmonary systolic murmur (see table of cases). Most decidedly it is the earliest to appear, it is constant in all postures and phases of respiration and is harsh and loud; it entirely replaces the first sound, and is the last bruit to disappear on recovery; indeed it may never fully disappear. We must consider this pulmonary systolic murmur in relation to the pulsation and dullness over the 2nd left costal cartilage and interspace, to be produced by a dilated pulmonary artery. The term 'hæmic or anæmic bruit' is a misnomer, and must be finally discarded, because a merely qualitative change in the blood is quite unable to produce a bruit. All bruits owe their origin to the same laws of physics, namely, the production of a 'fluid vein' whose vibrations are audible. We know that a fluid vein can only be produced if there is a relative change in the calibre of the orifice and the diameter of the exit tube. The blood must either pass through a constricted orifice, or pass out into a dilated chamber before a fluid vein can be formed and an audible murmur heard. We know that in epidemic dropsy, as the pulmonary capillaries are also dilated and engorged, the strain must fall on the main pulmonary artery, whose wall not being as firm and elastic as that of the aorta,

easily gives way and a dilated pulmonary artery is the result. Epidemic dropsy therefore impairs the integrity of the whole arterial system and we should regard the pulmonary systolic bruit as an expression of the widespread arterial damage in the pulmonary circuit. Further, the aorta is not spared. A well-marked supra-sternal and carotid pulsation along with a low systolic and diastolic pressure points to the same weakness of the wall of the aorta and carotid arteries. Finally, venous pressure is increased and, thus, no part of the cardiovascular system escapes injury in this disease. If we get this picture clearly fixed in our minds, we shall the better grasp the manifestations of this syndrome.

Rhythm.—Tachycardia is constant, with rates varying from 110 to 130 and rarely exceeding 140 per minute, and it is out of all proportion to the pyrexia. Other things being equal, the increased heart rate is a measure of the severity of the cardiac failure. Pulsus alternans is occasionally present. Towards recovery, an occasional extra systole may develop, and, later still, a sinus arrhythmia. While the A—V bundle of His may be irritable and conduction time quickened, there is never any delay or block of the main bundle or its branches.

Pulse.—A fall of blood pressure is the rule, including both systolic and diastolic. The diastolic reading falls to 30 mm. of mercury or even less, producing the water-hammer or Corrigan type of pulse of aortic leak. The arteries possibly develop a weakness of the walls but there is no arteritis, and the veins are over-filled in congestive failure. The capillaries, we have already stated, are markedly dilated so that the affected tissue looks angiomatous or hæmorrhagic from a distance. Occlusion or rupture of the vessels is a rarity. The typical pulse is soft, small, rapid and of low tension.

Heart: Late sequels.—While recovery from the acute attack is usual, the affected patients have a difficult future to face, especially those who have had the heart and capillaries badly affected. All these patients have ominous symptoms of a relapse as soon as they eat the affected rice of an epidemic year and are the first to become ill; it seems as if they had become permanently sensitized to the toxin. Leaving aside the bad years the majority of adults over thirty years of age confidently state that they are never the same again; they are easily susceptible to palpitation of the heart and swelling of the feet and have less than their usual capacity for exertion, as if a permanent loss of cardiac reserve had come about. Athletic younger men also complain they have not the same physical stamina as before. This condition is hard to explain because we have no evidence of permanent structural damage to the myocardium. We know, of course, that a severe attack of enteric fever, influenza or bacillary dysentery also frequently produces a permanent loss of cardiac

reserve, where also we have no proof of a permanent structural lesion in the myocardium, but, arguing by analogy, we may regard this as a definite fact. Yet, a real danger is lurking here. Ever since the epidemic of 1909 and 1910, this fact has been so much over-stressed that it has become almost an obsession with the patient and his doctor. Even to-day, people suffering with their hearts walk into the consulting room, place their diagnosis on the table and ask for the specific remedy. Frequently the patient is not carefully examined and is dismissed, well pleased with the advice, on calcium therapy and a rich vitamin diet. The true condition in elderly persons may be a syphilitic, a hypertensive, or a renal heart, a condition most dangerous to overlook. Far better is it to judge the case on actual physical signs than to pay too much attention to the history. These warnings are sounded as a result of experience with cardiac cases in Calcutta.

Blood.—The blood on venesection is very striking to the naked eye. The colour is dark chocolate instead of dark red: it clots almost at once; the clot is softer and more gelatinous; and the serum is bile-tinted. This is quite unlike the blood in uræmia or chronic heart failure.

Other manifestations

Fever.—Rise of temperature is an initial and fairly constant symptom and its degree is a rough measure of the severity of the illness, but with one possible exception (*see table*). Where diarrhœa is very severe and loss of body fluids extreme, a sub-febrile state is seen, although the illness is truly grave. Another feature is quite distinctive and unique. In no other disease do we find such a persistent difference in the temperature of the skin of the legs, as compared to that of the face. It would form a most interesting study to make simultaneous and serial observations of the temperature in different parts of the body, such as the skin of the legs, face, and axilla, and to check these readings with the rectal temperature. The dusky-red hot legs typical of the disease show these changes less markedly as the condition improves, until finally the leg temperature agrees with the general body temperature elsewhere. The erythema fades and may be replaced by a darkish pigmentation of the affected skin.

Diarrhœa.—In an earlier epidemic, diarrhœa was the exception and the cardiovascular system was so severely affected that a very high mortality was seen as early as the first week. This is explained by the absence of elimination and the locking up of the toxins. A moderate diarrhœa of about four to six motions a day is not so ominous. The other extreme, approaching the algid type with loss of body fluids, is of serious omen. The initial toxic diarrhœa is often the starting point of the malady and the typical Gram-positive bacilli are frequently met.

with. These were only detected in three patients of this series. The reason is probably that the majority of the patients came in for treatment when the disease was well developed. At this period probably other varieties of intestinal flora get the upper hand, overrun the typical rice bacilli and make them difficult to detect. This would explain our not finding them in all the samples examined and we would therefore stress the importance of immediate and repeated stool examinations at the very onset of the malady. Acton and Chopra (1927) frequently found in the stools of epidemic dropsy patients, when examined early in the disease, these Gram-positive bacilli, whilst in the controls the majority of organisms were Gram-negative bacilli with the ordinary Gram-positive cocci.

Knee jerks.—In typical beriberi, the knee jerks become exaggerated at first, but later diminish and may entirely disappear. Inflammatory changes in the nerves have been demonstrated in such cases. A perusal of the table of cases under review shows a similar state of affairs, though perhaps not to the same extent. In some patients the knee jerks were definitely exaggerated while in others they were markedly decreased, and this was also our experience in the other epidemics we have studied previously. There is thus undoubted evidence of the presence of neuritis in epidemic dropsy.

Treatment.—The lines of treatment adopted in our present series were the same as those used by Chopra and Basu (1930). Rice was entirely cut out from the dietary. It was definitely established that the progress was much slower if rice was allowed as a part of the diet. We have seen many instances of patients who, while under treatment, secretly took rice and had a relapse of all the signs and symptoms.

Diarrhoea, if mild, needs no treatment but if severe 15 to 30 minims of liquor ferri perchloridi are distinctly helpful. When there were signs of cardiac failure administration of digitalis and digitalis-like substances again proved a failure. From the discussion of the pathological changes met with in the heart it is obvious that digitalis can do little good when the muscle fibres of the heart are normal and are being pressed upon by fluid. Any drug, which might act on the small arterioles and capillaries and restore their tone and thus decrease the fluid pressing on the muscle fibres, ought to produce beneficial results. Adrenalin would bring about such a state of affairs and daily intramuscular injections of 2 to 4 minims of 1 in 1,000 solution considerably improved the condition of the patients. Unfortunately a sensitiveness to this drug develops after it has been given for a few days consecutively, and palpitation and a feeling of oppression in the chest are so distressing that the patient refuses to have the drug.

We have obtained good results with 20 to 30 minims of tincture of ephedra administered two

or three times a day either by itself or in combination with a little iron and strychnine. Ephedrine acts in very much the same way as adrenalin, its action being not so powerful but more prolonged. Further, large quantities of pseudo-ephedrine contained in the Indian ephedras have a marked stimulant action on the myocardium and the combined action of the two alkaloids makes this preparation a very useful remedy in the treatment of epidemic dropsy. Ten grains of calcium lactate two or three times a day if combined with the above treatment help in those patients where, on account of diarrhoea, there is a considerable drain of fluid from the body.

Discussion

Our discussion will be as brief as possible. The first thing is to discard, for the moment, all hypotheses which tend to obscure the issue and then to sum up all the known facts of ætiology, pathology and symptomatology: to endeavour to trace the path of intoxication and locate the habitat and destiny of the suspected toxins: finally, to build up a rational scheme of prophylaxis well understood by laymen, and a plan of therapy easily carried out by practitioners.

The ætiological factors require no further emphasis beyond the fact that our recent work tends to indicate the Gram-positive bacillus as the source of toxins partly formed outside the body and ingested as chemical poisons, and partly manufactured in the human gut. The pathological findings may be accepted as being the result of the disease, and not the remote effects of other mixed and secondary infections. A study of the pathology of the living indicates a 'cardio-capillary crisis' as being the most serious condition present, which leads to progressive heart failure and, occasionally, to death.

The path of intoxication starts with the ingestion of the affected rice. In the stomach and duodenum local irritation is produced which may proceed down to the rectum, causing areas of congestion and necrosis of the mucosa. Local injury to the rectal mucosa causes occasional vascular swellings which bleed profusely. The absorption presumably takes place through the liver which also shows the typical lesions and the antitoxic function of the liver is severely tested but fails, and finally the toxin reaches the general circulation. Although symptoms may commence as early as twenty-four hours after feeding, the effects of this intoxication are very severe and serious and may continue for some weeks after a rigid stoppage of the suspected food-stuff. This suggests a massive storage of the toxins, or a linkage with the cells of various tissues, such as is known to occur in heavy-metal poisoning, with lead or mercury, for example. Possibly the liver and the glands of secretion all along the bowel wall may be the

storage organs. The digestive juices and bile may be the medium whereby a daily dose is constantly released into the duodenum and thus the gastro-intestinal disturbances persist. The mechanism for destruction or neutralization of these toxins in the body is slow in action, if it does exist at all. The elimination takes place by the bowels and kidneys although evidence of an unnaturally toxic urine being passed is not forthcoming. We have seen cases relapse after an initial improvement and this can only be explained by supposing that, at times, a massive dose of this locked-up toxin is released into the general circulation and renders the 'cardio-capillary crisis' as bad as ever. Rational therapy might be summed up as follows:—

1. Stimulate elimination of the toxins by the bowels.
2. Neutralize or break down the toxins in the bowels into inert harmless products.
3. Prevent absorption of the toxin.
4. Stimulate the antitoxic power of the liver so that the toxins are broken down into simpler products.
5. Stimulate the defensive mechanism of the body whereby the ductless glands may produce hormones destructive to the toxins.
6. Quicken up the process of elimination by the kidneys.
7. Add to the diet, appropriate vitamins which may render the toxins inert.
8. Counteract the 'capillary crisis' throughout the body and thus hasten the process of circulation.
9. Support the heart by tonics.
10. Relieve the venous congestion by leeches or venesection.

In practice, however, all these ten points cannot be dealt with for want of exact knowledge but the prospect is far more

hopeful than might at first sight appear. We have, in the past, relied exclusively on cardiac tonics, in one or other shape, and have ignored the other vital therapeutic points. Since the heart is 'sinned against as well as sinning' this narrow view of therapy could not possibly give the best results. The 'cardio-capillary crisis' is best dealt with by that group of drugs which has a sustained vaso-pressor effect, combined with the power to counteract the increasing permeability of the minute capillary walls. It is fortunate that in ephedrine we possess a potent remedy whose optimum and selective seat of action is in the capillaries, and an extended use of ephedrine has fully confirmed the success which seemed likely. The digitalis group of drugs has failed us, because this capillary crisis is left untouched and until this is corrected no cardiac tonic can maintain adequately the circulatory process. In calcium we possess a means of decreasing the permeability of the capillary walls.

In a subsequent paper we hope to give a detailed analysis of all the epidemics that have been studied by the senior author during the past nine years.

	neighbourhood. Calcutta—4 years. (Disease started as diarrhoea which lasted for a day only; with the stoppage of diarrhoea the œdema of the legs appeared.)	systolic bruit loudest at the pulm. area. B.P. $\frac{88}{30}$ $\frac{P}{R} = \frac{120}{24}$ 2-9-32. General improvement. B.P. $\frac{100}{40}$ $\frac{P}{R} = \frac{100}{24}$ 21-9-32. General improvement, but liver engorged to the same degree; systolic bruit maximum in pulm. area. B.P. $\frac{102}{50}$ $\frac{P}{R} = \frac{88}{24}$	pituitrin, adrenalin, blood letting, leeches, potass. brom. Left hospital on own responsibility.
3	H., M., 5, generalized œdema, 2 weeks, preceded by fever for 4 days; rash on feet, solid type of œdema in legs; a few other family members affected; dysentery 6 months back. Barasat—all along.	Advanced congestive failure; jugulars, liver, lungs engorged; marked suprasternal and carotid pulsation; apex 6th and 7th interspaces beyond ant. axillary line; systolic bruit harsh and loudest over pulm. area; also typical mitral systolic over apex; short sharp first sound; mitral incompetence. B.P. $\frac{85}{40}$ $\frac{P}{R} = \frac{132}{40}$ 9-9-32. General improvement; liver $\frac{1}{2}$ inch smaller, right lung base congested; apex 5th interspace and $\frac{1}{2}$ inch less out; systolic bruit softer in all areas, but loudest over pulm. area. B.P. $\frac{90}{40}$ $\frac{P}{R} = \frac{116}{36}$	Gram-positive organisms (mostly staphylococci), yeast. B.T. 10 days after admission. Iron, strychnine, digifortis, atebria. Cured.
4	H., M., 2, fever, œdema, legs, one week; diarrhoea; rash, on both legs; a few other family members suffering from similar complaint; dysentery 6 months back. Barasat—all along.	26-8-32. Advanced congestive failure; jugulars, liver, lungs engorged; marked suprasternal and carotid pulsation; apex 6th interspace beyond ant. axillary line; systolic bruit harsh and loudest over pulm. area; also typical mitral systolic over apex; short, sharp, first sound. B.P. $\frac{80}{33}$ $\frac{P}{R} = \frac{124}{18}$ 9-9-32. Slight general improvement; liver $1\frac{1}{2}$ inches smaller; right lung base congested; apex 5th interspace and $\frac{1}{2}$ inch less out; systolic bruit in pulm. area only. B.P. $\frac{80}{30}$ $\frac{P}{R} = \frac{100}{40}$	
5	H., M., 7, œdema, legs, 3 weeks; fever 2 weeks; rash, legs; a few other family members suffering; malaria several attacks; dysentery 6 months ago; legs tense, red and glossy; loss of knee jerks. Barasat—all along.	23-8-32. Liver slightly engorged; apex 1 inch away from nipple; systolic bruit loudest at pulm. area. B.P. $\frac{88}{30}$ $\frac{P}{R} = \frac{120}{24}$ 2-9-32. General improvement. B.P. $\frac{100}{40}$ $\frac{P}{R} = \frac{100}{24}$ 21-9-32. General improvement; systolic bruit maximum in pulm. area. B.P. $\frac{102}{50}$ $\frac{P}{R} = \frac{88}{24}$	Gram-positive organisms. (No Gram-positive spore formers.) B.T. 10 days after admission. Iron, strychnine, tr. ephedra, mag. sulph., atebria. Cured.

Table of cases—contd.

No.	Race, sex, age and history	Cardiovascular manifestations	REMARKS
6	H., M., 32, fever 3 weeks; œdema, legs, palpitation, dyspnoea 2 weeks; erythematous rash (both legs); a few other members of the family suffering; dysentery 4 months ago; malaria in the past; knee jerks exaggerated (left more than right).	2-9-32. Liver, lungs engorged; jugular and suprasternal pulsation; apex 1 inch outside nipple; systolic bruit loudest in pulm. area. B.P. $\frac{105}{65}$, $\frac{P}{R} = \frac{88}{18}$ 21-9-32. General improvement. B.P. $\frac{105}{65}$, $\frac{P}{R} = \frac{84}{20}$	Gram-positive spore formers, morphologically similar to <i>B. vulgaris</i> . Agglutination against <i>B. vulgaris</i> (isolated from his own stool)—negative. Iron, strychnine, tr. ephedra, mag. sulph. Cured. He was admitted on 1-9-32 and discharged on 16-9-32. He went out but came back with palpitation. Palpitation became severe and he had to be propped up. He was cured of the symptoms after about 2 weeks and was discharged on 30-9-32.
7	H., M., 4, fever followed by œdema legs—12 days; dyspnoea off and on, rash, loose bowels in the beginning; a few other members suffering; several attacks of malaria; dysentery 6 months ago. Barasat—all along.	23-8-32. Marked venous congestion; jugulars full, pulsating; liver, lungs engorged; carotid and suprasternal pulsation; apex 6th interspace beyond ant. axillary line; right border dullness is 1 inch right of sternum; harsh systolic bruit loudest in pulm. area; typical mitral systolic over apex; mitral regurgitation. B.P. $\frac{96}{40}$, $\frac{P}{R} = \frac{140}{48}$ 9-9-32. Improved; carotids, jugulars pulsating; bruits in all areas. B.P. $\frac{95}{40}$, $\frac{P}{R} = \frac{116}{40}$	Single colony of Gram-positive spore formers, morphologically similar to <i>B. subtilis</i> . Agglutination against <i>B. vulgaris</i> (isolated from No. 6)—negative; Gram-positive organisms (mostly cocci). Iron, strychnine, quinine. Cured.
8	H., F., 24, œdema, pain legs 2 months; dyspnoea; knee jerks; right normal, left exaggerated; several members in the family suffering from similar complaints. All along in Barasat.	23-8-32. Carotid, suprasternal pulsation; apex—5th interspace, $4\frac{1}{2}$ inches out; harsh systolic bruit in all areas, loudest at the pulm. area; first sound short, sharp, mitral leak. B.P. $\frac{90}{50}$, $\frac{P}{R} = \frac{120}{40}$ 21-9-32. General condition much improved; systolic murmur in pulm. area only. B.P. $\frac{105}{60}$, $\frac{P}{R} = \frac{92}{24}$	Gram-positive organisms (mostly cocci); single colony of Gram-positive spore formers. Agglutination against <i>B. vulgaris</i> (isolated from No. 6)—negative. Iron, strychnine, pandigal. Cured.
9	H., M., 2, fever followed by diarrhoea, slight œdema feet (evening) 1 week, scabies; many other family members suffering from similar complaint; dysentery 6 months ago. Barasat—all along.	26-8-32. Suprasternal and carotid pulsation; apex—5th and 6th interspaces beyond ant. axillary line; systolic bruit loudest at pulm. area; typical mitral systolic over apex; first sound short and sharp; mitral regurgitation. B.P. $\frac{70}{30}$, $\frac{P}{R} = \frac{120}{40}$ 9-9-32. General improvement; apex—same position; murmur still loudest over pulm. area. B.P. $\frac{80}{40}$, $\frac{P}{R} = \frac{40}{R}$	B. T. (day of admission) very scanty Gram-positive organisms. Iron, strychnine, quinine. Cured.

CARBON TETRACHLORETHYLENE IN THE TREATMENT OF HOOKWORM INFECTION

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
and

A. K. MUKERJI, M.B.

(From the Hookworm Research Laboratory, School of Tropical Medicine, Calcutta)

CARBON TETRACHLORETHYLENE was first suggested for the treatment of hookworm infection by Hall and Shillinger (1925). It was tried by several workers in different parts of the world and most of these investigators gave favourable reports on its use. We (Maplestone and Mukerji, 1929) tried it and did not find it very efficient, but we were only able to obtain it in soft gelatine capsules each of which contained half a c.cm. of the drug. We administered the tetrachlorethylene both in the capsules and removed from them, in some cases combining it with oil of chenopodium and in others giving it alone. The number of cures obtained by all of these methods considered together only worked out at 20.7 per cent, which was less than half of that obtained previously with carbon tetrachloride used in the same sized dose and in similar combinations. In addition to its

apparent ineffectiveness we found that just as many persons suffered from giddiness, nausea and vomiting after taking tetrachlorethylene as they did after tetrachloride, and as we have never seen any more severe symptoms than these after the use of the latter drug in Calcutta we expressed the opinion that the two drugs appeared to be equally toxic as far as we could judge from the symptoms produced, and Brosius, Peon and Carroll (1927) came to the same conclusions as ourselves. We accordingly discontinued the use of tetrachlorethylene until Lamson, Brown and Ward (1932) pointed out that such symptoms as the above are not evidence of dangerous toxicity, but are only those produced by any diffusible stimulant. On account of this statement we obtained a fresh supply of tetrachlorethylene, this time not in gelatine capsules, and submitted it to a further trial.

Before using it again in the treatment of patients, however, we decided to test it on cats. Our reason for doing this was that when carbon tetrachloride was first recommended for treatment of hookworm infection it was said by American workers to be safe for both dogs and cats, but when Chandler and Chopra (1925) tested this drug on Calcutta cats they found it

unaccountably toxic to these animals, so we thought it better to test tetrachlorethylene in the same manner before again using it on human beings. The result of our work on cats has been given recently in a paper by Maplestone and Chopra (1933), where it was shown that in very large doses the drug causes death of cats with some damage to the liver and kidneys; it can be given to these animals in thirty times the relative dose we have used for human beings without causing more than slight congestion of the liver and kidneys, and without any damage to the cells of either. We have also shown that alcohol does not increase its toxicity, and so we feel justified in stating that it is a much safer drug to use than is carbon tetrachloride, and unless it is given to patients suffering from severe intercurrent disease it is unlikely to produce dangerous symptoms, much less death.

Tetrachlorethylene does not appear to have come into general use as an anthelmintic, and in the last three or four years little has been written about it. The most important paper is one by Lambert (1933) in which he records over 46,000 treatments with this drug in the South Sea islands without a death and without any untoward symptoms, but he notes that it has a more exhilarating effect than tetrachloride, which as we have explained above is not to be taken as evidence of toxicity. Garin, Rousset and Gonthier (1931) describe using tetrachlorethylene in doses of three grammes, four grammes and five grammes respectively on three consecutive days giving the drug in doses of one gramme at hourly intervals. They kept their patients in bed or confined them to their rooms during the treatment, so their method is not of any use for employment in the treatment of labour forces, but as the only symptoms complained of by their patients were drunkenness and giddiness immediately after taking the drug, their report indicates that tetrachlorethylene cannot be very toxic. Kendrick (1929) reported on about fifteen hundred treatments with tetrachlorethylene in doses of three c.cm., and in this series he had one man who exhibited severe symptoms. This patient appeared healthy but he soon became unconscious after receiving the drug, he remained in this state for about three hours, and he was so collapsed that it was thought necessary to give him an injection of strychnine and digitalin. After recovering consciousness this man rapidly improved and two hours later was apparently normal. Ten other persons were treated at the same time as this man with the same sized dose of the drug and none of them showed any signs of toxicity. The above is the only case of dangerous toxicity yet recorded from the use of tetrachlorethylene as far as we know, and so far there have been no deaths.

This isolated experience of Kendrick's suggests the possibility that a few persons exist who have an idiosyncrasy to tetrachlorethylene, just as there appear to be in the case of tetrachloride,

but the similarity between the two drugs ends here for tetrachloride always damages the liver and frequently the kidneys, whereas tetrachlorethylene does not have any damaging effect on these organs.

Method of administration.—In our previous work on this drug we found that it was similar to tetrachloride in that it was just as effective when given with the purgative as when the giving of the purgative was delayed for one or two hours. Accordingly we have followed the same routine in the use of this drug as we have previously employed in giving tetrachloride. For a considerable time before we began to use tetrachlorethylene we used tetrachloride and oil of chenopodium in combination in all our hookworm cases. Our reason for using the two drugs is that the cure rate is slightly higher than when tetrachloride is given alone, and as the majority of patients have an ascaris infection as well the oil of chenopodium acts on these worms too. The maximum dose of oil of chenopodium we employed in combination with tetrachloride is one c.cm., which is well within the safety limit of toxicity of this drug, and in the present series of cases treated with tetrachlorethylene we have used the same amount of oil of chenopodium as well.

The actual details of treatment are the following, which we have now used for some years in the case of tetrachloride without any ill-effects. It will be seen that it has the advantage of being both simple and cheap in that it does away with the use of gelatin capsules.

Two ounces of saturated magnesium sulphate solution are placed in a flask or bottle of three or four ounces capacity and four c.cm. of tetrachlorethylene and one c.cm. of oil of chenopodium are added to it. The flask is corked and shaken until the drugs are distributed throughout the mixture in the finest possible droplets; the dose is then given to the patient immediately, before the drugs have time to coalesce into larger drops and float to the surface, as they will do if the mixture is left standing. This method of shaking was adopted in the first place because it was stated that it was dangerous to give tetrachloride unless it was in finely divided droplets, and the same method has been continued with tetrachlorethylene because we consider that the even diffusion of the drug throughout the draught gives it a much better chance of coming into contact with all the worms on the gut wall and it is therefore more efficient than if given as an undivided globule of one drachm.

Although the work of Garin et al. quoted above indicates that tetrachlorethylene can be repeated with safety for two or three days in succession we do not recommend its being given under less than ten-day intervals, because it resembles other anthelmintics in causing the female hookworms to stop egg-laying for some days when it fails to remove them, and so the

establishment of a cure cannot be determined under that time.

Results of treatment.—We have treated fifty cases under hospital conditions and we have cured thirty-one (sixty-two per cent) with the first treatment and a further six (twelve per cent) with two treatments. The cure rate after the second treatment would probably have been higher but ten of the remaining thirteen persons left hospital before it could be given to them, thus there were only four patients out of the fifty that we definitely know were not cured by two treatments. Our standard of cure has been a negative result with Lane's centrifuge at least ten days after treatment, we have not made egg counts to estimate the percentage reduction of worms because as we have formerly pointed out (Maplestone and Mukerji, 1932) we consider deductions made from these counts unreliable.

Twenty-one of our patients felt slight giddiness, nine vomited, four felt nausea but did not vomit, and one said he felt drowsy for a short time. Of the nine persons who vomited two did so immediately and the others at periods ranging between one and three hours after swallowing the dose; the dose was not repeated so the vomiting probably had some effect on the total cure rate, and this supposition is supported by the fact that only two of the nine who vomited were cured by one treatment. This record of intoxication appears somewhat formidable at the first glance for the total number exhibiting symptoms appears to be thirty-five, but the actual number of individuals so affected was thirty as some of them showed more than one of the symptoms mentioned. Also it should be noted that the symptoms were never severe, and as we were dealing for the most part with uneducated persons the presence or absence of these symptoms had to be elicited by leading questions so it is possible that suggestion played a considerable part in deciding the nature of the replies given. Both Kendrick and Lambert, quoted above, also found that tetrachlorethylene is more exhilarating than tetrachloride, but with the exception of the one case of Kendrick's none of these symptoms were severe and only resembled those of alcoholic intoxication. Lambert says he has often observed coolies deliberately exaggerating the effects of tetrachlorethylene for the amusement they seemed to derive from appearing more drunk than their fellows. This is an important thing to remember when using the drug on a large scale with numbers of coolies being treated at once and looking on at the treatment of others.

After the work recorded in this paper was finished we noticed a paper by Christensen and Lynch (1933) in which, as a result of experiments on dogs, they state that tetrachlorethylene in therapeutic doses causes considerable depression of the heart and respiration, but they give no details as to the amount of the depres-

sion produced nor how it was estimated. On account of this statement we have tested these effects on ten patients. Our method of doing this was to take the pulse and respiration rates and the blood pressure immediately before giving the usual dose of tetrachlorethylene and oil of chenopodium, and to repeat these readings one hour and two hours afterwards. Our results are shown in the table.

TABLE
Effect of tetrachlorethylene on the respiration and circulation

Case number		TIME READINGS WERE TAKEN		
		Before dose	1 hour later	2 hours later
1	Pulse per min...	92	92	88
	Resp. per min...	18	22	24
	Blood pressure ..	120/65	110/60	114/54
2	Pulse per min...	72	76	80
	Resp. per min...	20	18	20
	Blood pressure ..	110/70	100/60	102/64
3	Pulse per min...	60	64	60
	Resp. per min...	20	20	20
	Blood pressure ..	100/60	105/60	100/65
4	Pulse per min...	68	68	60
	Resp. per min...	24	20	24
	Blood pressure ..	110/70	100/55	95/55
5	Pulse per min...	80	88	84
	Resp. per min...	20	16	20
	Blood pressure ..	120/95	114/90	114/85
6	Pulse per min...	68	64	68
	Resp. per min...	20	20	20
	Blood pressure ..	120/50	118/50	112/48
7	Pulse per min...	64	64	60
	Resp. per min...	20	20	24
	Blood pressure ..	120/70	114/68	104/60
8	Pulse per min...	88	80	76
	Resp. per min...	20	16	20
	Blood pressure ..	100/54	94/54	90/58
9	Pulse per min...	76	80	80
	Resp. per min...	24	20	20
	Blood pressure ..	100/62	94/64	96/64
10	Pulse per min...	80	68	60
	Resp. per min...	16	16	20
	Blood pressure ..	120/78	120/74	118/70

It will be seen from these figures that there is no constant or significant change in the pulse and respiration rates, and although there appears to be a definite tendency for the blood pressure to fall in all the cases this is so slight as to be negligible in practically every instance. With regard to changes in blood pressure it should be borne in mind that blood pressure is a constantly varying quantity and that it may be considerably influenced even by mild excitement. The patients we examined in this way were all

Indians of a low standard of education so that it is possible that the appearance of the sphygmomanometer and the manipulations attendant on taking the readings may have somewhat excited them and caused a slight rise of blood pressure on the occasion of taking the first reading when they did not know what was going to happen next, but as this element of uncertainty was absent on the two subsequent readings the blood pressure remained unaffected. In any case, whether the circulatory changes observed by us after administration of tetrachlorethylene were real or apparent, they are so slight according to the evidence obtainable by clinical examination that we are unable to agree with Christensen and Lynch when they say that it causes considerable depression.

These workers also say that tetrachlorethylene caused damage to the small intestine both in single and repeated doses, but we saw no macroscopic evidence of this in our work on cats so did not examine this organ microscopically. We have already published our results regarding the damage done to the liver and kidneys of cats (Maplestone and Chopra, 1933) and as far as our work went we cannot agree that this drug causes any appreciable damage to these organs when given in single doses much in excess of the therapeutic amount, and we are much more inclined to agree with Lamson, Robbins and Ward (1928) who consider tetrachlorethylene is safe in respect of the liver and kidneys. Christensen and Lynch also claim that considerable damage is done to the heart tissue by tetrachlorethylene. We have not yet made any experimental observations on the effect of this drug on the heart so we are unable to comment on their statement except to say that there is no clinical evidence of damage of this nature.

Our cure rate with tetrachlorethylene is slightly greater than it was with tetrachloride, but we gave one c.c.m. more of the former drug than we did of the latter, and this may explain the difference, but even if this is the explanation of the higher number of cures with tetrachlorethylene the practical advantage of it still remains, because if it can be safely given in larger doses than tetrachloride and cures more persons it is therefore a better drug for the purpose of curing hookworm infection. The price of tetrachlorethylene is slightly higher than that of tetrachloride at present, but that is of little importance because from the price quoted by one firm of manufacturing chemists we find that a dose of four c.c.m., or one drachm, will only cost half an anna.

Conclusion

Tetrachlorethylene, used after the method described above, is at least as efficient as tetrachloride, and it is safer than the latter on

FEVERS IN PREGNANCY

By M. SARKAR, B.A., M.B., F.R.C.S.E.

Second Professor of Midwifery and Second Surgeon,
Eden Hospital, Medical College, Calcutta

IN our experience at the Eden Hospital, *Bacterium coli commune* infection of the urinary tract has been found the commonest cause of fever in women during the period of gestation. Seventy-two pregnant patients were admitted into the Eden Hospital with fever in the year 1932, and of these 57 (79 per cent) had *B. coli* infection of the urinary tract.

Why should *B. coli* infection be so common with pregnancy? Various explanations have been offered, and it is generally agreed that the infection is blood-borne. Horder is of the opinion that constipation, which is very common during pregnancy, is responsible for minute ulcerations ('fretting' is the term used) in the mucous membrane of the large intestine. Through these ulcerated areas *B. coli* gain access to the blood and lymph streams. They are

(Continued from previous column)

account of its not damaging the liver and kidneys when given in therapeutic doses. Another great advantage, especially when dealing with a large labour force, is the fact that alcohol does not increase its toxicity.

forthwith excreted through the kidneys if functioning normally, but usually there is a mechanical obstruction to the flow of the urine from the pelvis of the kidney to the bladder during the first few months of pregnancy. The rising uterus tends to press on the ureter, at the brim of the pelvis. The uterus reaches there at the fifth month and symptoms appear in the majority of the cases from that month onwards. The pressure, no matter how slight, is enough to obstruct the free flow of urine and the pelvis of the kidney or kidneys dilates slightly and there is an incipient hydro-ureter and a consequent hydronephrosis. The retained urine harbours the *B. coli* excreted from the blood and a mild pyelitis results, manifesting itself by fever, dysuria and pain in the back. The pain is usually unilateral and is commoner on the right than on the left side; this is due perhaps to the normal dextro-deviation of the uterus. Superficially this explanation seems convincing but obviously it is not final, because we have not been able to grow *B. coli* from the blood stream of all patients suffering from pyelitis during pregnancy. We have tried to prove the mechanical part of the theory in the following manner. In an intelligent primipara who was admitted with fever in the eighth month of pregnancy, the presentation was changed from a vertex to a breech and the uterus was pushed to beyond the middle line on the left side and kept there with pads, and an abdominal binder was applied. The nurse was instructed to make the patient lie on the left side and not to allow her to lie on her back. Twelve hours afterwards the patient said that her pain was gone, and the dysuria was much less but there was no difference in the temperature. Encouraged by this experiment, a routine podalic version and a forced sinistro-deviation of the uterus has been done on six cases, with appreciable relief of pain but without any remarkable difference in the excursions of the temperature.

An Armenian patient, a primipara, was admitted into the hospital thrice between her fifth and ninth months, each time with high fever. A pure growth of *B. coli* was obtained every time from the urine. On the last occasion this patient died in a condition of coma two hours after admission. A post-mortem Caesarean section was done to recover a living child if possible, and the opportunity was availed of to inspect the kidneys. Both the pelves were distended and the ureters, when exposed, were found to be dilated.

It is far from easy to treat these cases of pregnancy pyelitis. Like benign tertian malaria a single attack can usually be controlled, but it is a very obstinate infection to eradicate completely. The first step in the treatment is to empty the bowels with a suitable purge by mouth, followed in two or three hours time with a bowel wash of normal saline containing two grains of potassium permanganate to the pint.

The next step is to administer alkalis in massive doses till the urine is completely alkaline. Our practice is to prescribe citrate of potassium in drachm doses repeated three or four times in the day because bicarbonate of soda is not tolerated by these patients. It has been found that a good way of giving the potassium salt is in combination with a tablespoonful of glucose 'D' (Sandoz) or sugar-of-milk dissolved in a wine-glass of water. After intensive alkaline treatment acids are exhibited, acid sodium phosphate in ten-grain doses is administered followed by a ten-grain cachet of hexamine twice or three times a day. Acids are not tolerated by some patients and they complain of either frequency of micturition or actual burning during the act. If this occurs the treatment is immediately discontinued and the bladder may have to be washed out with normal saline and it is advantageous to put one ounce of a one per cent solution of mercurochrome into the bladder. When there is actual cystitis a self-retaining catheter is introduced into the bladder and kept there for a couple of days. Oral administration of hexamine is not always so effective as it is by the intravenous route. In all protracted cases of fever of *B. coli* origin a course of intravenous injections of 5 c.cm. of a 40 per cent solution of urotropin is very useful. Once the temperature is well controlled or moderated to excursions of a degree or a degree and a half per day, Horder recommends salol and hydrargyrum cum creta in five-grain doses by the mouth twice daily for four days in the week.

Vaccines have not been found very efficacious in the treatment of the *B. coli* infection during pregnancy. Pathologists explain this failure by the fact that they do not always get a pure growth from the culture of the urine. Stock vaccines or autovaccines prepared from a culture of the urine have not proved of any use in the limited number of cases in which we used them. Mr. Wade of Edinburgh irrigates the pelvis of the kidney with normal saline solution in obstinate cases. We have not had the opportunity of trying this method of treatment. Passing a ureteral catheter is useful in that it dilates the strictures in the ureters and makes it possible for the urine to flow more freely.

Malaria and kala-azar are not such frequent complications of pregnancy as might be expected from the prevalence of these diseases in this part of the world. In fact primary malarial infection during pregnancy in an Indian is a rare event. In a series of 21 cases of primary malarial infections during pregnancy, 4 were Europeans, 1 was an American, 1 a Japanese, 3 were Chinese, 8 were Anglo-Indians and the remaining 4 were Indians whose previous history of having fever was indefinite. The American, the Japanese, and two of the three Chinese patients had come to this country within three months of being infected and, of the nine

foreigners, in seven the infection was that of a malignant tertian fever. In our limited experience at the Eden Hospital and at a maternity and child welfare clinic run by a missionary society in Calcutta, the incidence of kala-azar during pregnancy is infrequent. In one year in a series of 1,940 cases, the sera of only 17 patients running a temperature were returned as positive to the aldehyde and urea stibamine tests. In addition to these, in 32 cases where the clinical picture was one of kala-azar, urea stibamine was tried empirically with very good results. In our hands quinine has not yet interrupted the course of pregnancy in patients where the malarial parasite has been found in the blood and where the patient has been given alkalis along with the quinine. We never use quinine intravenously but only by the oral or intramuscular route. We tried atabrin in three cases of benign tertian infection with encouraging results and we did not meet with any discoloration of the skin. We have not used plasmochin.

Intestinal parasites are very often responsible for the febrile condition during pregnancy. Gurkha women and people from the Northern parts of the adjoining areas of Bihar and the United Provinces suffer from heavy helminthic infections.

Intra-uterine death of the foetus occasionally is the cause of a rise in the temperature. In the early months of gestation the ovum may separate from the wall of the uterus, totally or partially. If it is not expelled it remains in the uterus as a carneous mole. The rise in the temperature may be due to the absorption of fibrin from the intra-uterine extravasated blood. In the later months when interruption in gestation occurs, disintegration of the foetus, the placenta and the membranes takes place and absorption of these products possibly reacts on the mother, producing 'fever'. Beyond the rise in temperature and a feeling of malaise there may not be any definite indication pointing to the death of the foetus. If the symptoms are not urgent, it is safe to wait for a fortnight, or if possible for a month and, at the end of the period, examine the uterus to find out if it has enlarged in size. If the uterus remains stationary or retrogresses, suspicion as to the death of the foetus is confirmed. In more advanced pregnancies absence of foetal heart sounds and foetal movements, where there were such sounds and movements previously, clinches the diagnosis at once. X-rays help the diagnosis in advanced cases. A flattened and deformed calvarium, a hyperflexed or super-extended spine, and irregularly placed limb bones all point to the fact that the foetus is dead and the skeleton is in the process of intra-uterine maceration. It is easy to empty the uterus of the products of conception in the later months, but in the early months it is not always

TOXIC EFFECTS OF EPHEDRINE—A WARNING

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

and

B. MUKHERJEE, M.B.

(From the Department of Pharmacology, School of Tropical Medicine, Calcutta)

THE alkaloid ephedrine is obtained from several species of ephedra growing in China and India. Under the name of *Ma Huang* this herb has been in use in the Chinese indigenous medicine for about 5,000 years. The development of a useful modern drug out of this ancient remedy is due to the pioneer work of a Japanese chemist, Nagai (1887), who isolated this alkaloid in a pure form and two Japanese physiologists, Amatsu and Kubota (1917), who demonstrated the essentially sympathomimetic (epinephrine-like) effects produced by ephedrine. Chen and Schmidt (1924) reopened the therapeutic possibilities of the drug by conducting a series of careful studies with regard to its physiological properties. Chopra and his collaborators (1929, 1930, 1931) did a large amount of work on the Indian species of ephedra and worked out many points in connection with the pharmacological action and therapeutic properties of not only ephedrine but the allied alkaloid, pseudo-ephedrine.

The result of all this work has been that during the last ten years ephedrine has risen from obscurity to a widespread popularity among medical men in all parts of the world.

(Continued from previous column)

so easy. The placenta is in most cases adherent and does not separate easily. We use and recommend the very safe and simple technique of introducing laminaria tents into the uterus along with the injection of glycerine and tincture of iodine into the uterine cavity. This operation is carried out as follows:—The patient is in the lithotomy position; no anaesthetic need be used. Two or three laminaria tents are introduced into the uterine cavity the first day, and after twenty-four hours these are removed, a thick india-rubber catheter (no. 12 Jacques) is introduced into the uterine cavity through which pure sterile glycerine and tincture of iodine (seven drachms of glycerine and one drachm of iodine) is injected into the uterus. At the same sitting three or more fresh tents are introduced. The uterus usually empties itself completely after this but occasionally four half-hourly injections of 0.25 c.cm. of pituitrin may be necessary.

The above observations have been made under the guidance of Lieut.-Colonel V. B. Green-Armytage, M.D., F.R.C.P., F.C.O.G., to whom I am grateful for allowing me to use the records of the Eden Hospital and to publish records of some of his patients.

Its range of utility is so wide that there is hardly a medical practitioner who has not had occasion to use the drug some time or other in the course of his professional career. The therapeutic claims made for the drug were examined by the Council of Pharmacy and Chemistry of the American Medical Association in 1926 and they were so struck by the potency and usefulness of the alkaloid that it was at once introduced into the United States Pharmacopœia. The new sixth edition of the British Pharmacopœia published in 1932 has also recognized it and it has now become an established remedy.

At the present time this alkaloid is widely used for a variety of conditions and the literature is full of many interesting and instructive articles regarding its pharmacological action and therapeutic uses. It has been used with success in the treatment of bronchial asthma, hay fever, whooping cough, bronchitis, postural hypotension and Stokes-Adam's syndrome. It has been employed in combating the fall of blood pressure in spinal anæsthesia, in antagonizing the action of narcotic drugs, in shrinking the congested nasal mucous membrane, and in dilating the pupil for ophthalmic examinations. Its effects in allergic dermatitis, shock and dysmenorrhœa are promising. Of all the diseases for which the drug has been tried, asthma is the commonest condition. The fact that it can be effectively given by the mouth and that its action is more lasting than epinephrine has made it a very popular remedy. Its reputation as an efficient anti-asthmatic has spread even amongst laymen and in many cases the drug is taken on a patient's own initiative without his consulting a physician.

From time to time attention has been called to certain untoward effects from the use of this drug whether given by the mouth or by injection. Miller (1925) by using doses of 50 to 125 mgm. (0.75 to 1.87 grains) found no definitely harmful effects but recorded that a few patients complained of palpitation, nervousness and nausea. One who had marked myocardial degeneration showed a transient pulsus alternans one hour after the drug was administered. Production of nausea after administration of the drug in cases of asthma and hay fever was reported by Althausen and Sehmacher (1927). Anderson and Homan (1927) used ephedrine in whooping cough in children. Though the drug was efficacious in preventing the spasmodic attacks, they observed in several cases marked restlessness, sweating, abdominal pain, discomfort, and apparent suppression of urine. That these symptoms were produced by ephedrine is shown by the fact that they disappeared when the drug was discontinued and reappeared when it was resumed. Middleton and Chen (1927) in a series of 41 patients found that palpitation of the heart was the prominent feature when the dose of ephedrine was larger

than 80 mgm. (1½ grains); vomiting, dizziness, nervousness, headache and insomnia were also observed in several cases. Tremors, weakness, sweating, and sometimes a feeling of warmth all over the body were also noted. These symptoms usually abated shortly after the blood pressure began to fall; this fall occurs in one to seven hours after administration. Four out of eleven cases in this series showed extrasystoles of ventricular and auricular origin after ephedrine which could be demonstrated with the electro-cardiograph. Another patient developed paroxysms of tachycardia which lasted for a few minutes at a time and then stopped. Bloedorn and Dickens (1928) described a case of cardiac asthma in which cardiac embarrassment, including pulsus alternans, marked tachycardia and cardiac decompensation occurred after administration of ephedrine. Pennetti (1928) observed, by means of electrocardiography, that ephedrine increased the frequency of pre-existing extrasystoles in two cases but produced no change in a case of auriculo-ventricular block of vagal origin. Chopra and his co-workers (1929) first pointed out in this country the dangers which may attend the indiscriminate use of this alkaloid. During recent years a number of cases have come to our notice which leave little room for doubt that the serious effects of the alkaloid have not been fully appreciated by the medical profession in this country. An analysis of the history sheets of a large number of patients in our asthma clinic revealed the frequency with which certain unpleasant side-effects were produced following the administration of ephedrine. We have therefore thought it necessary to give the results of our experience and sound a note of warning regarding its indiscriminate use.

TOXIC EFFECTS

Acute onset.—The most usually noted unfavourable symptoms in our series have been those referable to the *cardiovascular system*. Acute precordial pain resembling an attack of angina with palpitation and profuse sweating, particularly on the forehead, has been found quite commonly. In many persons these symptoms are not acute enough to be particularly noticed or to call for any immediate attention or interference. Tremors of the extremities; a feeling of warmth, flushing all over the body and a dull throbbing sensation in the region of the temples have not uncommonly been complained of by the patients. Faintness; loss of muscular tone and disinclination to physical exertion were observed in two patients. Other symptoms were irregular and rapid pulse, widely dilated pupils, feeble heart beats, and dyspnoic type of respiration. In fair patients, a distinct flush in the malar regions and over the ears may be noticeable.

Disagreeable symptoms in connection with the *gastro-intestinal tract* are less commonly met

with. Nausea, vomiting and colic have been complained of by at least four individuals in our series. Both vomiting and nausea become more intense if the drug is given after a heavy meal. Nausea is sometimes intractable and continues for 24 to 36 hours, but generally disappears within 8 to 10 hours after the drug is stopped. Abdominal distress and a peculiar vague feeling of discomfort round the umbilicus were complained of by two patients. Loss of appetite is not infrequently produced. Constipation with associated flatulence and distension has been a common complaint in those taking the drug for prolonged periods.

Affections of the *genito-urinary system* are observed in the form of dysuria, anuria, and spermatorrhœa. One patient reported complete retention of urine for 24 hours after the administration of ephedrine (4 tablets in the course of 24 hours). No reliance was placed on his version but the presence of a fully distended bladder left no room for doubt. Application of heat and a gentle pressure from above helped him to pass large quantities of pale yellow urine easily. No reason for the retention of urine other than the use of ephedrine could be found in this case, and our opinion was corroborated by the fact that the condition recurred three days later when the drug was again taken and again disappeared when it was discontinued. Dysuria has been the prominent symptom in several patients. In one of these, albumin could be detected on examination of urine. There may be complete relaxation of the bladder sphincter resulting in involuntary micturition in some cases. Spermatorrhœa was complained of by two patients; one of them, a chronic asthmatic aged 46 years, refused to take the drug as it always induced a watery discharge from his urethra. Curiously enough, increase of sexual power has been reported by another who came back for the drug more for the aphrodisiac effects which he experienced than for the relief of asthma.

Many of the untoward effects referred to above have been noticed to occur in groups in the same individual. Thus, patients showing circulatory reactions usually complained of precordial pain, sweating, palpitation, flushing and tingling sensations simultaneously; very seldom has a single symptom been complained of. The effects become apparent within half an hour after administration of a dose and in the majority of individuals they pass away within 2 to 7 hours. Plethoric patients with systolic pressures above 120 to 130 mm. Hg. are more prone to get these side-effects.

In our series of patients we found that the toxic symptoms usually appeared in those who were having large and frequent doses of the drug. Doses below two grains daily rarely produced any symptoms except in sensitive individuals. No definite statement however can be made with regard to the relationship between

the dose and the appearance of the side-effects. The same dose may produce desirable and remarkably good effects in one patient but may produce equally beneficial results with some discomfort in another and may usher in a train of most undesirable symptoms in a third. According to Pollak and Robitschek (1926) and Gaarde and Maytum (1927) the development of these uncommon signs and symptoms does not depend so much upon the dosage but upon the stability of the nervous system of the individual taking the drug. We have at least two cases in our series in which we can definitely associate the appearance of these symptoms with a neurotic or a neuropathic tendency. Severe headache, faintness and a feeling of numbness in the extremities followed within twelve to fifteen minutes of administration of a half-grain tablet of ephedrine sulphate in one of these patients. Such cases fortunately are rare.

Ephedrine is considered to be a sovereign remedy against asthma and it is used more indiscriminately in this than in any other condition. Many of these cases are not true bronchial asthma and it is not unusual to find cases with involvement of the cardiovascular system being treated with ephedrine. If some of the toxic manifestations referred to above occur in cardiac cases, results may be dangerous. The following two cases are given by way of illustration:—

Case 1.—An Anglo-Indian working girl, aged 24, presented herself at the out-patient department of the School of Tropical Medicine, Calcutta, complaining of shortness of breath, cough, palpitation and a sinking feeling in the chest. She was diagnosed as a case of asthma by a private practitioner and was recommended an antispasmodic mixture and ephedrine hydrochloride tablets (gr. i each) at bed time or with the onset of an attack. The first night after only one tablet the patient felt fairly comfortable and slept well without any cough or paroxysm. The next day she had a busy day in the office and had to exert herself a little more than usual. That night there was a feeling of oppression in the chest, and palpitation and cough returned with increased intensity. She took three tablets of ephedrine one after the other. Within fifteen minutes she felt a sensation of giddiness and a sinking feeling; the precordial pain became intense and she felt that she was going to die. She was put to bed immediately, an ice bag was applied to the head and medical aid was sought. The patient however felt better by the time the doctor arrived but the pain in the chest remained in spite of the stimulants that were administered. Next morning as the asthmatic paroxysm persisted the patient took two more tablets without consulting the doctor, and the symptoms recurred with greater intensity. On examination she was found pale and cyanotic with dark rings round her eyes. She was using the accessory respiratory muscles when she talked and there was an anxious expression in her face. The tonsils were enlarged and slightly congested; râles were heard at the bases of both the lungs. The heart was definitely dilated with a rapid weak beat and a systolic bruit was audible at the mitral area. Systolic blood pressure was 120 mm. Hg., and diastolic 110 mm. Hg. Albumin and hyaline casts were found in the urine.

She gave a history of having rheumatic fever six years ago and another attack two years back. A diagnosis of asthma probably of cardiac origin was made and the patient was admitted into the Carmichael Hospital for

Tropical Diseases. In the hospital she was more thoroughly examined and the symptoms definitely attributed to heart failure. There was nothing to show that she was suffering from bronchial asthma. Ephedrine was tried in small doses and was found to aggravate the symptoms of cardiac failure and produced the symptoms above described. She was put on absolute rest in bed and digitalis, and the symptoms disappeared in the course of a fortnight.

Case 2.—A Hindu lady, aged 50, had been suffering from asthma for the last six years. She was treated outside with antispasmodics, vaccines, soamin, adrenalin, nasal cauterization, etc., without relief. She has taken ephedrine times without number for relief of paroxysms and always keeps a bottle by her for use in case of emergency. During the last attack for which she came under observation, she gave a history of having taken four ephedrine tablets within 1½ hours. Immediately there was a sensation of discomfort, precordial pain and distress which became unbearable. There was a hot flush all over the body and the abdomen was distended; flatulence, nausea and palpitation were very distressing. The patient also had intense headache and pain in the eyeballs.

Physical examination revealed a definitely dilated heart and thickened arteries, the chest was emphysematous (barrel-shaped) with sunken lower intercostals. The pulse rate was 100 per minute and there was evidence of missing beats. The blood pressure was rather high (155 mm. Hg. systolic and 130 mm. of Hg. diastolic) indicating hypertension. Albumin and granular casts were detected in the urine.

Ephedrine was discontinued and there was no recurrence of the symptoms. The patient was put to bed and kept under alkalies and digifortis and made a good recovery.

Chronic poisoning.—Prolonged use of ephedrine in therapeutic doses does not usually produce cumulative toxic effects. Individuals who suffer from paroxysms of asthma every night are enabled to remain free from attacks for long periods by taking this alkaloid in doses up to one grain once, twice or even three times every 24 hours. They can attend to their daily work and pass comfortable nights without any permanent ill-effects on the system. Experimental results also appear to bear out these observations. Middleton and Chen (1927) reported a case that received a total quantity of ten grains of ephedrine sulphate in a period of eleven days but showed no untoward effects. Wu and Read (1927) mentioned a case in which ephedrine therapy was continued for three years and caused no ill-effects. Chronic ephedrine poisoning however occurs though it is a much rarer condition. A pale, sallow and cyanosed appearance associated with a mild degree of anaemia has been frequently noticed in individuals who are in the habit of taking ephedrine for prolonged periods. Whether this is due to any toxic action of the drug or a natural sequence of the disease itself cannot be definitely stated without a thorough investigation on this point being made.

Habit formation is another undesirable result though it is debatable whether this ever occurs. It is common knowledge that gradually increasing doses are required by patients with chronic asthma for the relief of their attacks. This indicates increased tolerance if not actual habit

formation. In several of our patients we have noticed a peculiar sensation of euphoria produced by the drug. Withdrawal in those cases gives rise to a very uncomfortable feeling and the patients urgently demand to be allowed to resume the drug. Extreme nervousness and insomnia are also frequently met with. There was definitely some craving, though it was certainly not so intense as that felt after narcotic drugs. Whether this craving for the drug is a danger-signal of the early manifestation of a drug habit, or is due to the eagerness of the patients to ward off an impending attack it is very difficult to say. This observation is not in accord with that of Middleton and Chen (1927) and Thomas (1926) who believe that ephedrine is not a habit-forming drug. Higgins (1929) reported a case of chronic ephedrine poisoning which simulated hyperthyroidism in all its essential features, but we have not come across any case similar to the one described by him.

Discussion and comments

There is ample evidence to show both from a study of our own cases and from those recorded by other investigators that toxic manifestations and undesirable side-effects are not uncommonly met with after the use of ephedrine in asthma and other conditions. Some of the subjective symptoms are easily explained when one considers the physiological action the alkaloid produces on the system. Ephedrine in doses of 1 to 10 mgm. per kilogramme is known to cause a rise in blood pressure of anaesthetized dogs by 100 or more millimetres of mercury and it is maintained at this level for at least 15 to 25 minutes. In human beings, the rise in pressure is not so high as in animals but it varies from 20 to 65 mm. Hg. It is therefore easy to see that circulatory reactions like palpitation and anginal pain will be produced by the drug, particularly when the systolic pressure is at its highest level. The symptoms are also found to disappear as the pressure returns to normal. Insomnia and tremors are possibly due to stimulation of the central nervous system. Constipation, nausea and anorexia may be explained by the paralytic condition of the gut due to sympathetic stimulation and loss of tone. Headache and throbbing sensations in the temples may be attributed to changes in pressure in the arterioles or veins within the skull.

There is no agreement regarding the dosage required to produce these effects. Ephedrine is undoubtedly not a very toxic alkaloid and consequently there is a wide margin of safety. Its minimum lethal dose when given intravenously in dogs was found by Chen to be from 70 to 75 mgm. per kilogramme body weight. From this it can be inferred that a man weighing 50 to 60 kilogrammes would require about 4 to 5 grammes of the alkaloid to produce a fatal result. In contrast to this the usual therapeutic dose is from $\frac{1}{2}$ to 2 grains (65 to 130 mgms.)

and 7 grains (0.43 gramme) have been given in a single dose without untoward effects. The only explanation of the toxic effects appears to be a state of hypersensitiveness of certain individuals to the drug. Ephedrine is a sympathomimetic drug and stimulation of the sympathetic system in a highly-strung individual may lead to symptoms of sympatho-parasympathetic imbalance. It is also well known that slight differences in the amount of calcium in the blood make the autonomic system very sensitive to sympathomimetic drugs of which ephedrine is one.

Cautions and contra-indications

It should not be forgotten that ephedrine administration sometimes gives rise to unpleasant and dangerous side-effects. The commonest effects are attributable to its stimulant action on the circulation. All cases of asthma should therefore be thoroughly examined with regard to their heart condition before the drug is administered. Great caution should be exercised in using the drug in cardiac disorders especially when there are signs of failing compensation. In angina pectoris the drug is very dangerous. In chronic asthmatics with emphysema and arterial hypertension, ephedrine should not be prescribed.

Individual sensitiveness plays a great part in the production of the unfavourable symptoms. A small dose for one individual may be a large one for another. When in doubt the best plan is to test the sensitiveness of the patient with small doses, say 10 mgm., and establish the maximum tolerated dose. It is only by experience and judgment that these side-reactions can be reduced to a minimum. According to the experience of early investigators, a single dose of 50 to 100 mgm. for an average adult may be given with safety. Hess advocates the use of 1 to 2 mgm. per kilogramme of body weight, but this dose appears to be somewhat large for ambulatory patients. Our own experience indicates that in uncomplicated cases 25 to 30 mgm. ($\frac{1}{2}$ grain) is sufficient to relieve the paroxysm if the drug is going to act at all and if necessary the dose may be repeated two or three times during 24 hours. In complicated cases with secondary bronchial infections, a slightly larger dose may be necessary, i.e., from 60 to 75 mgm. (1 to $1\frac{1}{2}$ grains), and it is not advisable to overstep these limits. In cases which are not of an allergic nature and which are suffering from secondary bacterial infections and other complications such as emphysema, myocarditis, hypertension, albuminuria, etc., ephedrine, though helpful, does not relieve the condition satisfactorily, and it is no good increasing the dose in the hope of getting better results. Arteriosclerotic changes and permanent hypertension have been experimentally produced in rabbits by repeated injections of adrenalin over prolonged periods. Ephedrine

is a sympathomimetic drug belonging to the same class and has a very similar physiological action. When prescribing the drug to patients for indefinite and prolonged periods this should be borne in mind.

Summary

1. Ephedrine is a powerful drug and should be used with caution.
2. The toxic symptoms met with in patients in the authors' experiences have been described in detail.
3. In patients with high blood pressure, cardiac damage and history of anginal attacks ephedrine should not be given. In diagnosing cases of asthma, great care should be taken in separating cardiac asthmas from bronchial asthmas.
4. Ephedrine is quite effective in doses of $\frac{1}{2}$ to 1 grain (30 to 60 mgms.). In adults this dose can be repeated. The cases not relieved by such doses are not suitable for ephedrine treatment.
5. If during the administration of ephedrine, the patient exhibits any toxic symptoms such as palpitation, tachycardia, arrhythmia and vasomotor disturbances, the drug should be discontinued at once. Indiscriminate use of the drug may lead to serious results.

BRONCHOSCOPY IN ASTHMA AND OTHER CASES

By E. H. EVANS, M.D.

*St. Luke's Hospital, Friends Leprosarium,
Hillside Sanatorium, Vengurla*

CECIL (1930) states that, 'Asthma is produced by a narrowing of the lumen of the bronchi probably throughout the entire bronchial tree, either by spasm of the bronchial muscles or by œdema of the bronchial mucous membrane or both'. He also states that, 'Adrenalin chloride injected subcutaneously can control almost any attack for a time varying from minutes to hours'. This is the accepted view of the pathology and primary treatment. Of course, as he states, the underlying causes are many and are to be sought out and eradicated. Occasionally, however, we find a case which is apparently unaffected by the subcutaneous injection of adrenalin chloride. And in this type of case bronchoscopy has given brilliant results. Moore (1925) studied, histologically, sections of the bronchial mucous membrane of asthmatics who had come to autopsy. In many of these sections there was an absence of cilia, which meant that mucus accumulated in the bronchi could not be readily and naturally expelled. Jackson says, 'In cases studied bronchoscopically during an attack, the bronchi were found filled with tenacious bubbling secretions..... The secretions were removed (by aspiration) and the attack quickly subsided. In many cases a complete cure resulted, in a few others little or no influence on the recurrence of attacks was observed'.

Our first opportunity to try this treatment came in the form of a coolie who had travelled a long distance. He was a Marathia, aged 35 years, who said he had been suffering from cough and dyspnoea for one year. The salient features of the physical examination were two loose teeth, which the patient refused to have extracted, a barrel chest, a few râles at the bases and intense dyspnoea. He was admitted and treated with adrenalin injections, calcium lactate powders and a mixture containing potassium iodide, ammonium bromide, lobelia and stramonium. At the end of two days there was practically no improvement and he consented to bronchoscopic aspiration. During this procedure, the bronchial mucous membrane appeared slightly paler than normal and a small amount of thick tenacious mucus was aspirated from the main bronchi and from the principal branch bronchi.

The patient had a quiet night and the next morning I found him sitting up in bed, and saying that he had not been so comfortable for a whole year. He was discharged the third morning thereafter. This bronchoscopic aspiration was done in January and he was so grateful that I believe he would have returned in case of a recurrence.

During the year ending 1st May, 1933, we have had twenty-three cases where endoscopies on the food and air passages have been performed. They are classified as follows:—

Bronchoscopies for exploration and aspiration	13
Bronchoscopy for foreign body, a tamarind (chinch) seed in the right main bronchus	1
Laryngoscopies, exploratory or for biopsy or removal of tumours from the lower pharynx and larynx	5
Œsophagoscopies, exploratory or for biopsy or treatment of stricture of the œsophagus	4
TOTAL	23

Three interesting cases of the year beside that of the patient suffering from asthma are reported as follows:—

I. U. C., a Goanese hotel proprietor, aged 50, was admitted to the hospital on 28th November, 1932, with a history of fever, cough, foul expectoration and weakness. The symptoms began 21 days before admission with chills and blood in the sputum. Over the lower lobe of the right lung there was marked dullness, also coarse bubbling râles, distant breath sounds and coarse friction rubs. An x-ray plate could not be taken at the time but it seemed clear that the case was that of a lung abscess of the lower right lobe.

On bronchoscopic examination thick pus was found in the right main bronchus. About three ounces of this was aspirated. Then when the aspirating tube was pushed farther down into a branch bronchus, suddenly there was a rush of fluid and twenty-two ounces of watery blood-tinged fluid was aspirated. The most likely explanation of this seems to be that after aspirating the abscess cavity the aspirating tube punctured the lung and the blood-tinged fluid was from the right pleural space. Disastrous sequelae were anticipated but after the procedure the patient's temperature steadily declined and he regained strength. The cough continued troublesome and there was a moderate amount of sputum, but it was no longer foul. After seventeen days, bronchoscopic aspiration was again performed and only half an ounce of pus-like secretion was aspirated. The patient made a slow but steady recovery and was discharged on the 7th February, seven weeks after the second bronchoscopy. He had gained 13 pounds.

II. K. M. B., a man of 40 years, complained of hoarseness of two months' duration. Mirror laryngoscopy showed a tumour of the right arytenoid cartilage, a fullness in the region of the right false cord, hyperemia of both cords with almost complete paralysis. There was residual saliva in the pyriform sinus. Externally there was no palpable glandular enlargement. The larynx could be moved freely but with slight pain. The Kahn test was ++ and anti-syphilitic treatment was begun immediately. But since there is always the possibility of epithelioma of the larynx being coexistent with syphilis, a direct laryngoscopy with the Jackson laryngoscope was performed. A picture similar to the above, but clear, was seen. There was no sign of ulceration but the right arytenoid cartilage was markedly enlarged and hyperemic. The right cord was completely paralysed, the left almost completely. A portion of tissue was removed for pathological examination. This showed no evidence of epithelioma and the anti-syphilitic treatment was continued. The hyperemia and swelling of the right arytenoid rapidly diminished but the paralysis of the cords continued. Here the

SPREAD OF CUTANEOUS LEISHMANIASIS ALONG LYMPHATICS

By SANGHAM LAL, M.B., F.R.C.S.
CAPTAIN, I.M.S.

and

J. R. DOGRA, M.D.
CAPTAIN, I.M.S.

A SEPOY, Gurkha, aged 19, was admitted to hospital on 25th February, 1933, with a chronic ulcer on the dorsal aspect of the left middle finger and a similar one on the back of the right thigh.

Past history.—The patient was in hospital with the same complaint in January 1933, when he was given a course of 2 per cent tartar emetic, after which he improved and was discharged from the hospital in the middle of February.

On admission, he showed a large oriental sore of typical appearance on the dorsum of the left middle finger near its base and another on the back of his right thigh. Scrapings from these showed Leishman-Donovan bodies. On the dorsum of the left hand, he also showed numerous small hard painless nodules which he first noticed on 22nd February, 1933.

During his stay in the hospital new, hard and painless nodules continued to appear on the back of left forearm and a few along the basilic vein in the lower part of the arm. These

(Continued from previous page)

result of the biopsy taken by means of the direct laryngoscope gave us confidence that we were dealing only with syphilis and were not delaying during the growth of an epithelioma.

III. E. F., a widow, of 55 years, complained of pain in the neck below the cricoid cartilage, and of being able to swallow only liquids during the three weeks prior to admission. A mirror examination of the larynx was negative. The Kahn test was negative and there was no other evidence pointing to syphilis.

Upon œsophagoscopic examination the cricopharyngeus muscle was passed with difficulty and just below this a stricture of the œsophagus was found. The œsophagoscope passed this stricture however and entered the stomach with no other abnormality being discovered. Three days later a Plummer hydrostatic œsophageal dilator was passed and the water pressure raised until the dial indicated ten pounds pressure. The patient could endure this dilatation for only about 15 seconds because of fright at threatened suffocation. (The rubber bag of the dilator in this case covered the entrance to the larynx.) However, after the procedure she was able to swallow solids and felt so much relieved that she requested two more hydrostatic dilatations at three-day intervals. She left the hospital evidently completely cured and has not been heard of since.

- Cecil, R. L. (1930). *A Textbook of Medicine*. Second Edition. Philadelphia: W. B. Saunders Company.
Moore, W. F. (1925). Ciliary Inhibition or Destruction in Tracheobronchial Asthma, with Notes on Bronchoscopic Treatment. *Amer. Journ. Med. Sci.*, Vol. CLXIX, p. 799.

nodules were not fixed to the skin and were distributed along the course of the lymphatics. The axillary glands were not enlarged. The accompanying illustration shows the nodules on the back of the hand and forearm. Blood Wassermann reaction was negative.

Illustration showing the ulcer on the finger and the nodules on the hand and forearm.

Some of the nodules on the back of the hand softened gradually. On puncture 2 to 4 cubic centimetres of turbid fluid was withdrawn from each nodule which on direct smear showed Leishman-Donovan bodies, but no other organisms. Cultures on bacteriological medium were also sterile.

One of the nodules on the forearm was excised. On section it showed fluid as described above. Microscopically granulation tissue was seen. No Leishman-Donovan bodies, however, could be detected.

A few of the nodules on the dorsum of the hand ulcerated.

Treatment.—The patient was given a course of 10 injections of neostibosan intravenously: total dose of 2.5 grammes. During the course of injections there appeared to be no effect on the nodules most of which, however, disappeared within a week of the last injection. The ulcers had dried up and nearly healed when he was discharged.

No similar nodules were seen or felt in the vicinity of the ulcer on the thigh.

Conclusions.—Apparently the spread of leishmaniasis in this case occurred along the lymphatics, presumably by permeation along these channels. This mode of spread is considered worthy of note.

We wish to thank Lieut.-Colonel J. F. James, I.M.S., Officer Commanding C. I. M. H., Razmak, for permission to investigate this case.

(Note.—The spread of the leishmania infection along the lymphatics in cases of oriental sore has often been noted before, but the occurrence is certainly of sufficient rarity to warrant publication of this note.—EDITOR, I.M.G.)

ANIMAL PARATYPHOID IN GUINEA-PIGS

By Asst. Surgn. C. M. E. EYLES, I.M.D.
andNo. 2167. Sub-Asst. Surgn. BACHAN SINGH, I.M.D.
District Laboratory, Maymyo

THE following investigation of an outbreak of animal paratyphoid among the guinea-pigs of this laboratory may be of interest to other laboratory workers.

Housing, feeding, etc.—The pigs are housed in two separate rooms on which a run abuts, the rooms being used alternately every other day. Owing to the heavy rains at Maymyo the animals spend most of the time inside (at any rate this applies to the period during which the outbreak occurred).

The animals are fed twice daily on a diet of bran, oats, *gram* and vegetable peelings in lieu of lucerne grass; the peelings are supplied daily by a contractor and procured by him from the local market. Bedding in the shape of dry grass is supplied nightly. The number of guinea-pigs at the end of October was about 150, the animals being somewhat overcrowded.

The outbreak

The first casualty occurred in late October—a rather old pig—and presuming this to be just a case of death from old age we took no action. In the light of further happenings, how grave an omission this proved to be will readily be seen, and will go to show the importance of carrying out a post-mortem examination on all animals dying of an unknown cause, as it is not unreasonable to presume that this was the start of the epizootic.

Within a couple of days of this first casualty, it was noticed that most of the animals were off their feed, being rather lethargic with somewhat ruffled coats; very heavy rain was registered at this time. On the third of November three more pigs died and several others were very ill indeed. From this day onward between two and eight animals died daily, and in spite of every endeavour on our part to stop the outbreak, this state of affairs continued unabated up to the third week of November, when it more or less abruptly ended, leaving us with but seventy pigs—a loss of eighty animals in a period of three weeks.

Post-mortem and cultural findings

On two of the three animals that died on 3rd November post-mortem examinations were carried out; both revealed peritoneal exudates with deep congestion of the small intestines and greater curvature of the stomach, the small intestine showing ulceration and patches of hæmorrhage in the ileum (probably inflamed Peyer's patches). The liver and spleen were congested as also the lungs; there were no signs of scurvy and the suprarenals were somewhat anæmic. A culture was made from the heart's

blood and in both cases *B. enteritidis* was isolated. Post-mortem examinations were carried out on over thirty animals in all, and, with few exceptions, all showed the same morbid changes in varying degrees. Cultures of the heart blood were made in ten cases; five were positive, three were contaminated and no serious attempt was made to recover the organism from these, and two proved to be sterile. In all positive cultures an abundant growth was noted within twenty-four hours. Glucose broth was initially used, but ordinary nutrient broth gave as good results. The ulcerated patches from the intestines in three cases were washed in saline and the washings plated on litmus lactose agar, innumerable colonies of *B. enteritidis* were isolated from these plates. Cultures made from the fæces and stomach contents were less successful for, after many attempts, only one plate proved to be positive; nor could we isolate the organism from the fæces of any sick animal; this appeared to us strange, considering that the utmost care in technique was observed and in most cases only samples that appeared fresh were used. Blood cultures from the hearts of sick animals were more successful, for out of six cultures taken three were positive.

Serological findings

(a) *Guinea-pigs.*—The sera of four animals were taken post mortem and put up against emulsions of *B. enteritidis*, isolated from previous cases; all gave agglutination in dilutions varying from 1 in 50 to 1 in 250.

The sera of three sick pigs were also tested for agglutinins; two gave agglutination in dilutions of 1 in 125 and 1 in 250, the third showed no agglutination. All three animals died later showing characteristic post-mortem changes and from the heart blood of one of them *B. enteritidis* was isolated. Two healthy animals were also tested, but failed to show any agglutinins; it is of interest that these two tests were carried out early in the outbreak. Later, a pooled serum (that used as complement for the Wassermann) was put up and gave agglutination in a dilution of 1 in 250; naturally these sera were from apparently healthy animals. Two healthy animals, tested later still, gave similar results; this would suggest that almost all the pigs were affected to some degree and had developed immunity; but we must here state that—with one exception—every animal that showed signs of being ill died.

(b) *Rabbits.*—The serum of two rabbits housed with the guinea-pigs was also tested; both gave total agglutination in dilutions of 1 in 250. This would appear to bear out our opinion that rabbits are either naturally immune or readily acquire an immunity; but it is only fair to state that these tests were also carried out at the tail end of the outbreak. None of the rabbits, however, appear to have been infected.

(c) *Sheep*.—The sera of two sheep belonging to the laboratory, but housed quite separately, failed to reveal the presence of any agglutinins. All serological tests were controlled as a routine but no auto-agglutination was observed.

Course of disease

The course of the disease was between 4 to 10 days, the first appreciable symptom being an absolute loss of appetite, the animal soon took to a corner where he sat with ruffled fur evincing no further interest in life. Within a couple of days the animal appeared very ill indeed and its condition might well be compared to the typhoid state in man. Diarrhoea was absent in most of the cases, which was strange in view of the post-mortem findings. A few cases developed paralysis of the hind legs, subsequent post-mortem examination in those cases revealed no signs of scurvy. Pregnant females aborted.

Source of infection

The probable source of infection was the vegetable-peeling supply. Cultures were made from the scrapings and washings of peelings supplied, but in no case were we successful in isolating the organism. The spread of the infection was enhanced by overcrowding, rendered worse by the inclement weather at the time, causing the animals to be huddled together for the greater part of the day.

Preventive measures

These consisted of daily flushing out of rooms and run with cresol, spraying the walls and shelves with a solution of formalin—a Flit sprayer being used for the purpose, segregation of all sick animals, burning of bedding, excreta, corpses, etc., and washing all vegetables with a solution of permanganate.

Feeding experiments

In order to study the disease further two guinea-pigs were fed on cultures of *B. enteritidis*. One of them was given a drop from a saline washing and the other a platinum loop from an agar slope; this was done on two consecutive days, but not concurrently. The incubation period would appear to be from two to four days, and the symptoms the same as those previously described. The organism is apparently much attenuated in culture for both animals survived. Prior to the experiment the sera of both animals were tested for the presence of agglutinins; the first showed agglutination in a dilution of 1 in 50, the second was negative. In the first experiment a blood culture was not taken when the pig was ill, as we intended doing this when the animal died; the heart's blood taken later (10th day) when the animal was recovering was sterile. In the second case, profiting by our previous experience, a blood

culture was taken on the fifth day of disease and was positive, the serum causing agglutination in a dilution of 1 in 25. Repeated examinations of the faeces in both cases were negative, and in neither case was there any evidence of diarrhoea.

The following is a daily record of the second guinea-pig; the course of the disease in the first was very similar.

11-11-1932.	590 grammes.	Serum giving no agglutination.
12-11-1932.		Fed with an inoculated platinum loop from agar slope.
13-11-1932.		Do.
15-11-1932.		Ruffled fur. Loss of appetite.
16-11-1932.	550 grammes.	Looks ill.
17 & 18-11-1932.		Very ill. Faeces negative.
19-11-1932.	530 grammes.	Blood culture positive, agglutinins present 1 in 25.
21-11-1932.		Looking better. Faeces negative.
22-11-1932.	560 grammes.	Improving, eating well.
24-11-1932.	570 "	
26-11-1932.	570 "	Appears well.
28-11-1932.	580 "	
30-11-1932.	590 "	Released, quite well.

The following points appear to us of special interest:—

1. The severity of the infection and high mortality; at the commencement of the outbreak we had 150 pigs, and in the course of three weeks this number was reduced to 70. Of the naturally-infected animals, all but one succumbed.

2. The preponderance of deaths among the female pigs; the proportion of females to males affected was about 5 to 1, and we were left with only 5 females at the end of the outbreak. Without exception, all pregnant pigs aborted.

3. The apparent absolute immunity of rabbits; over 20 rabbits were housed together with the pigs under identical conditions, not a single animal was affected; they flourished and bred quite happily in spite of the fact that scant attention was paid to them at the time.

4. The apparent immunity of young pigs; at the commencement of the infection we had 30 young pigs housed in a separate cage. They did well, only two dying during the period, strange to say, both females; post-mortem examinations carried out on these animals did

not reveal any morbid lesions, nor could we isolate any organism from the heart's blood.

The milk of infected animals would appear not to be infective. Two full-term litters, of two each, lost their mothers on the fourth and

fifth days respectively. An attempt to rear them on diluted cow's milk was of no avail, all four dying within a week. Post-mortem examinations carried out on these animals failed to show any characteristic lesions and their heart's blood was sterile.

A Mirror of Hospital Practice

A CASE OF DYSIDROSIS TREATED BY CALCIUM

By S. R. INGLE

Medical Officer, Mirajgaon, Ahmednagar District

Dysidrosis is a common disease, occurring in young people mostly in the heat of summer, and the usual methods of treatment adopted for this condition appear to be unsatisfactory. The results obtained in the case reported below are thought to be of sufficient interest to justify publication.

Case record

An otherwise healthy Mahomedan boy, aged about 20, consulted me on 10th March for eruptions of about a month's duration on the palms of his hands and toes. For the last four years, he has been suffering from these eruptions which come on every summer, are preceded by a sensation of itching and tingling, and which disappear spontaneously at the approach of the cold season. He always suffers from somewhat excessive perspiration of the hands and feet. There is nothing of importance as regards his past or family history.

When first seen on 10th March, he had symmetrical eruptions, consisting of vesicles and bullæ over the palms of his hands, the sides and webs of the fingers and to a less extent on the toes. Some of the blisters were discrete whilst others had coalesced forming large bullæ, and if one of them was punctured, it exuded slightly turbid fluid, exposing a tender and raw surface. The boy complained of pain, tenderness and itching and consequently suffered from sleeplessness. There were no constitutional symptoms. Physical examination was negative.

Treatment.—During the first four days, the patient was given twenty minims of dilute hydrochloric acid, well diluted in water, and five-grain salol powders, thrice daily after meals. Locally a lotion containing liquor plumbi subacetatis fort., zinc oxide and calamine was ordered; but this gave him no relief. During the next four days, calcium lactate in 10-grain doses thrice daily was tried without any benefit. In the second week, four intravenous injections each consisting of one gramme of calcium gluconate in ten cubic centimetres of water were given and the following lotion and ointment was ordered for local use:

R Liq. plumbi subacetatis fortis.

Liq. carbonis detergentis .. aa. ʒi.

Aquam ad ʒxii.

Sig.:—To be used frequently for cleansing hands and feet.

R Calaminæ preparatæ

Zinci oxidi aa. gr. xxx.

Hydrargyri ammoniati gr. x.

Paraffinum molle ad ʒi.

Sig.:—To be rubbed well in at bed time.

INTESTINAL OBSTRUCTION RELIEVED BY ATROPINE

By R. K. SANYAL, M.B.

Patuakhali, Barisal

FOLLOWING the reports in the *Indian Medical Gazette* of the successful reduction of strangulated hernia after atropine injection I have used it in the two following cases with excellent results:—

INTUSSUSCEPTION

Case 1.—A Mahomedan boy, aged about 12 years, had suffered from intermittent pain in the abdomen for a week. There was a sausage-shaped mass about three inches in length situated transversely in the transpyloric line. The mass changed its position on standing and lying and appeared to be connected with the transverse colon. It could also be made to move up and down by manipulation. During this time the boy passed very little stool, but blood and mucus were passed several times a day and there was considerable tenesmus. The abdomen was not much distended and there was slight tenderness over the tumour. The patient had occasional attacks of vomiting and there was visible peristalsis in the abdomen. The case was diagnosed as intussusception of the transverse colon. A soap-and-water enema was given and the fluid was heard by the stethoscope to flow up to the tumour. The enema was returned and the tumour remained unchanged, but the abdominal pain rather increased. Atropine sulphate 1/100 grain was injected and after three hours the pain disappeared. Twelve hours later I went to see the patient and found that the tumour had already disappeared.

STRANGULATED HERNIA

Case 2.—A Hindu male, aged about 45 years, had had an inguinal hernia on the left side for a long time. Up to the present occasion he had always been able to reduce it himself, but this time he neglected it for some time and then found he could not reduce it.

Taxis was unsuccessfully tried by another practitioner and after about twelve hours I was called to see the patient and found a left inguinal hernia of the size of a big mango. It was very painful on pressure and there was no impulse on coughing. The patient was in

great distress and his pulse was weak and quick. I tried taxis but failed. Atropine sulphate 1/50 grain was then injected hypodermically and Goulard's lotion applied over the herniated mass, and a hot compress over the inguinal canal. In fifteen minutes the pain had disappeared and the patient fell asleep. The hernia gradually became reduced and after six hours it had completely disappeared.

EIGHT CASES OF PLAGUE TREATED WITH 'BAYER 205'*

By RAO SAHEB R. D. PARULKAR, M.B., B.S.

Medical Officer of Health, Municipal Borough, Bijapur

In the last plague epidemic of 1932-33 the routine treatment of plague cases at the Municipal Infectious Diseases Hospital was intravenous iodine and a stimulant mixture. After reading the successful results with 'Bayer 205' reported by Dr. B. R. Ranganatha Rao, L.M.P., in the *Indian Medical Gazette* of November 1932, I treated the following eight cases at the hospital by this method. All of the patients were given an intravenous injection of 'Bayer 205' in 10 c.cm. distilled water, and an injection of 1 cubic centimetre of 1/1000 adrenalin on the day of admission. In addition they had a stimulant mixture, were kept in bed on a milk diet, and had belladonna plasters applied to the buboes.

Case 1.—Hindu male, aged 55. History of two days' illness. Removed from his house to hospital on 6th December, 1932. On admission his temperature was 103°F., pulse 135 of low volume and easily compressible and respirations 25. He had diarrhoea the previous day. Tongue—partially paralysed and dry; speech—not clear, delirious at night. There was a tender bubo in the right groin. The next morning the temperature fell to 100.5°F. and pulse to 90 and it was of fairly good volume, and he had no delirium the previous night. On 8th December, 1932, he was given 1 c.cm. adrenalin injection and stimulant mixture and there was no change in his condition as his temperature was 100.5°F. and pulse 100. His relatives were unwilling to keep him in the hospital and so he was removed to his house on the evening of the same day. I examined him in his house on 9th December, when he had a temperature of 103°F., pulse—140 and respirations—30. On 10th December he had a temperature of 104.5°F., irregular pulse—145 and respirations—50. He died on 11th December at 9 A.M.

Case 2.—Mahommedan female, aged 30. History of illness—three days. Removed to hospital on 7th December, 1932. On admission her temperature was 102.5°F., pulse—20 and respirations—20. She was conscious and her speech was clear but her eyes were congested. There was a tender bubo in the left axilla. Next day her temperature came down to 99.5°F. and pulse to 90. She was given 1 cubic centimetre of adrenalin injection and routine stimulant mixture. But on 9th December the disease took a serious turn and she had a temperature—103°F., pulse—120 and respirations—24. Her pulse became rapid and irregular and respirations were 45 on 10th December although her temperature was 100.5°F. She died on 11th December, 1932.

Case 3.—Mahommedan female, aged 25. History of illness—three days. Removed to the hospital on 8th December, 1932. On admission her temperature was

103.5°F., pulse—135 and respirations—20. There was a tender bubo in the left axilla. Next day her temperature came down to 103°F., pulse—135 and respirations—18. On 14th December her temperature was 99.5°F. with pulse 120 and respirations 20. She had normal temperature on 15th December. Her relatives removed the patient to their home in the evening of 15th December. She died on 19th December, 1932, in her house.

Case 4.—Mahommedan male, aged 55. History of illness—two days. Removed to the hospital on 8th December, 1932. On admission his temperature was 103.5°F., pulse—135 and respirations—20. There was a tender bubo in the right groin. Next morning his temperature was 103°F., pulse—130 and respirations—22. On 14th December his temperature fell to normal, and he was discharged cured on 15th December, 1932.

Case 5.—Hindu female, aged 30. History of illness—three days. Removed to the hospital on 20th December, 1932. She was unconscious; eyes—congested; temperature was 105°F., pulse—145, irregular, and respirations—45. There was a tender bubo in the right groin. She died the same night.

Case 6.—Hindu female, aged 30. History of illness—two days. Removed to hospital on 4th January, 1933. There was a tender bubo in the right groin. Her temperature was 103°F., pulse—140 and respirations—30. Next day she had the same temperature but respirations were 35. On 7th January her temperature was 104°F., pulse—145, irregular, and respirations—55. She died in the evening of the same day.

Case 7.—Hindu female, aged 15. Removed from the jail premises to the hospital on 11th January, 1933. Her temperature was 103°F., pulse—150, respirations—25. Next day her temperature came down to 100°F., pulse—130 and respirations—25. But on 15th January the temperature rose to 105°F., pulse—140 and respirations—40. Her lungs showed signs of patchy consolidation. She was given a six-gramme camphor injection in the morning and six grammes in the evening. On 17th January her sputum was rusty, temperature—104.5°F., pulse—150, irregular, and respirations—55. Her relatives removed her to her village 12 miles away, where she died the next day.

Case 8.—Jain male, aged 40. History of illness—two days. Partial paralysis of tongue. Eyes—congested. Admitted to hospital on 13th January, 1933. His temperature was 105.5°F., pulse—140 and respirations—30. Next morning his temperature was normal with pulse 120 and respirations—25. Till 18th January he had a normal temperature and pulse—100 but respirations increased to 30. On 19th January he lost the power of speech, the tongue became dry, temperature—98°F., pulse—100 and respirations—40. On 21st January, 1933, his pulse became rapid and irregular and respirations—55, and he died in the evening of the same day.

Only one out of eight persons treated by 'Bayer 205' recovered, therefore the drug does not appear to be of much use. At the same time it should be stated that most of the patients had severe pneumonic complications, so it is not possible from these results to express an opinion on the value of 'Bayer 205' in uncomplicated bubonic plague.

CONGENITAL ABSENCE OF THE EYES*

By P. R. PRABHAKAR

State Hospital, Mirpur (Jammu State)

In the course of out-patient work in the above hospital a child aged two months was shown

* Rearranged by Editor.

* Rearranged by Editor.

to me by the mother, who gave the history that it had never opened its eyes. At first it seemed that the two eyelids were adherent, but on further examination it was found that they were retracted and that both eyes were completely absent. This condition must be extremely rare because I have not been able to find any mention of it in the books at my disposal.

I wish to thank Dr. Fazel Rahman for permission to publish this note.

[Note.—Professor M. N. De, Professor of Pathology, Medical College, to whom we showed the above report, has kindly supplied us with the following note on this condition:

Complete absence of the eyes, which is usually a bilateral condition, is met with in healthy well-developed children, and is often associated with other malformations, such as hare lip, supernumerary digits, etc. As a rule, the eyelids are well formed but may be adherent at the margins. The orbit is usually smaller than normal and is lined by conjunctiva. In all such cases, digital examination will reveal either a cystic or a hard mobile nodule at the extreme apex. The lacrimal gland is usually present. The nodular mass is composed of the subsidiary parts of the eye derived from the mesoblastic elements. There is, however, a complete absence of the essential nervous elements constituting an eye.

This condition, though very rare, is occasionally met with in the out-patient clinics of any big hospital and is a well-recognized form of developmental anomaly of the eyes.—EDITOR, *I. M. G.*

SPASMODIC STRICTURE OF THE GULLET

By M. A. KRISHNA IYER, L.M.P.

Medical Officer, Tirutani, Chittoor District

The following case seems worth recording:—

A woman, aged about 30, was brought to me with a history of some difficulty in swallowing. She was partaking of dinner at a marriage party at 11 p.m., when suddenly, at the end of the meal, she thought she swallowed a big ant or beetle when drinking water. Immediately she felt a choking sensation. She tried to drink more water but could not swallow a drop. Many attempts to force water down her throat not only failed but produced an intense feeling of suffocation. She was brought to me at about 11-30 p.m. I gave her a cup of water and asked her to sip, but she could not swallow and the few drops of water practically choked her. By means of an electric torch I examined the throat and found nothing abnormal. I introduced my finger and inserted it as far as it would go, and found no obstruction. The patient appeared to be of a nervous temperament. When asked to shut her mouth firmly and breathe through her nose, she did so for about five minutes without feeling any discomfort. I brought a rubber tube and told her that I was going to introduce it into her mouth and push the obstructing material down. She tried to resist, but her relatives held her firm. Though I tried many times I could not put the rubber tube through the mouth. Therefore I introduced it through her nose. When the tube had gone in about one foot, she began to cry out and say that she was better and that the tube could be removed.

I removed the tube and gave her a cup of water. She drank it freely and asked for more, which was given. She was taken home quite recovered.

The points for note are:—

(1) She could not swallow even a drop of water.

(2) The act of swallowing apparently sent the water into the trachea and hence produced a feeling of suffocation.

(3) The symptoms were real and not feigned.

(4) The tubing went in freely and there was no obstruction felt.

(5) Though nervous, she could not be considered hysterical.

On these grounds I made a diagnosis of spasmodic stricture of the oesophagus.

AN UNUSUAL STRANGULATED HERNIA

By C. H. REINHOLD

LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, Lucknow

PURBU DIN, aged 35, a Parsi villager had an inguinal hernia of several years duration which became strangulated about the end of April. After eight days of harsh village treatment his serotum ulcerated and relief came with the formation of a faecal fistula. He was admitted into the Bahampur Hospital on 4th May, two days after.

He was very emaciated and showed marked toxæmia and the surroundings of his wound were unhealthy. After feeding and cleaning him up for a few days to improve his condition, I

Fig. 1.—Faecal fistula in serotum.

decided to do a lateral anastomosis above the herniated loop, and this was effected through a para-rectal incision on 15th May; the hernia was of the small gut. The patient made an uninterrupted recovery, the wound healing by first intention; but unfortunately, the faeces continued to pass through the fistula.

A second operation was done on 24th May, through an incision along the upper half of the inguinal canal, the herniated loop in the canal was cut across and an end-to-end anastomosis of the two upper ends of the gut was effected. This wound also healed without incident, and the bowels at once began to move naturally.

The faecal fistula at once stopped discharging faeces but a small sinus persisted from which mucus exuded, coming from the remnant of bowel left in the sac.

A third and final operation through an inguino-serotal incision was therefore undertaken on 14th June and the loop of bowel was

Fig. 2.—Lateral anastomosis above hernia.

Fig. 3.—End-to-end anastomosis through hernia.

removed without sacrificing the integrity of the cord. The man finally left hospital on 2nd July having put on more than a stone in weight.

All the operations were performed under per-caine spinal anaesthesia and the patient never complained of any headache or caused us a moment's anxiety.

I have to thank my house surgeon Dr. R. S. Gupta, M.R.C.P., for his unremitting attention to the case.

SPINA BIFIDA WITH MENINGO-MYELOCELE*

By A. K. CHANDA, L.M.F. (Bengal)
Medical Officer, Bhikasin Hospital, Almora,
United Provinces

THE following case occurred recently in my practice :—

History.—A child was born with a small swelling the size of a betel nut over the lumbar region of the spine. This gradually increased in size and there was gradual thinning of the skin covering the swelling. At the age of five months it was the size of an orange and was very soft in the centre. A local *vaidya* diagnosed it as an abscess and made a small incision into it. Watery fluid escaped and for the next twenty-four hours the child gradually collapsed. At this stage I was called in.

Examination.—Patient very weak and drowsy, cannot suck the mother's breast. Pulse weak and rapid. The posterior parts of the arches of the 3rd and 4th lumbar vertebrae are absent and the space is occupied by a soft swelling into which an incision has been made; and from the incision, when the patient moves, cerebrospinal fluid escapes. There are bands of adhesions between the superficial covering and the interior of the swelling, dividing the cavity into compartments.

Diagnosis.—Spina bifida with meningo-myelocele.

Treatment.—Disinfection of the surrounding parts, injection of the cavity with 10 c.cm. of normal saline, closure of the opening by sutures, and firm bandaging.

The patient improved for twenty-four hours but on the third day collapse occurred, and the patient died on the fourth day after operation.

A LARGE PEDUNCULATED LIPOMA ON THE NECK*

By J. SATYANARAYANAMURTI, L.M.F.
Sub-Assistant Surgeon (Reserve Duty), Government
Head-Quarters Hospital, Nellore

A MAN aged about sixty was brought to me while I was in charge of a dispensary at Kunavarum, Upper Godavari agency.

He had a large pedunculated tumour situated on the back of the neck. This tumour first made its appearance about forty years ago and since then it had gradually increased in size. The growth never caused any pain and the man had always refused operation. Recently, however, he allowed a friend in his village to open it with a sickle with the idea of letting out the contained fluid. This 'operation' only caused pain and suppuration so the patient came to me and agreed to have the tumour removed.

Under local anaesthesia this was successfully done and the tumour was found to weigh about eleven pounds. On section it appeared to consist of soft fatty material interspersed with dense fibrous tissue.

NOVEMBER

BERI-BERI AND EPIDEMIC DROPSY

BERI-BERI has been recognized as a distinct disease by the Chinese for many centuries, and mention of it is also found in Japanese writings of the seventeenth and eighteenth centuries. Our modern knowledge of beri-beri may be considered to have begun with the work of Bontius in 1642, and in 1835 Malcomson wrote an excellent description of this disease. Epidemic dropsy is probably just as ancient, but it was not until 1877 that McLeod, during a famine in southern India, first suggested that it was different from beri-beri. The controversy raised by McLeod's suggestion has raged fiercely until the present day and there are still some eminent workers who consider that beri-beri and epidemic dropsy are not distinct diseases.

The reason for this confusion is that the epidemiology and symptomatology of the two diseases are very similar. Both are found in races for whom rice is the staple article of diet, and they are both liable to appear suddenly and to affect large numbers of the community in a short space of time. The principal symptoms of these diseases are polyneuritis, œdema and cardiac hypertrophy followed by dilatation of the heart, often acute. Beri-beri may appear either as the 'dry' type in which there are heart lesions but little or no œdema and in which the main symptoms are due to an extensive peripheral neuritis, or it may be the 'wet' type in which œdema is the principal sign and the neuritis is not so marked. Wet beri-beri has a close clinical resemblance to epidemic dropsy and the two conditions may be difficult to distinguish; it is this superficial resemblance that has led to the confusion which is only now disappearing. Close study of epidemic dropsy during recent outbreaks has shown that it differs from beri-beri in that the characteristic peripheral neuritis is absent and that gastrointestinal irritation, a peculiar mottling of the skin, and hæmorrhages from the mucous membranes, none of which are seen in beri-beri, are common symptoms.

Before the advent of modern biochemical methods and the establishment of the fact that vitamins are important ingredients of all diets if health is to be maintained, many theories as to the causation of these diseases were put forward by different workers, and although these theories are of little importance in the light of modern knowledge it may be of interest

to give a brief recapitulation of them to show how we have gradually reached our present state of knowledge regarding the ætiology of these diseases. Calcium deficiency in the blood, diminution in the amount of circulating proteins producing lowered osmotic pressure and consequent œdema, intoxication from a diet of unsuitably-dried fish, and mustard-oil poisoning have each been suggested as causes of the disease, but modern research has not supported any of these theories.

Takaki of the Japanese navy was the first to suggest food deficiency as a cause of beri-beri; he believed that insufficient protein was the factor, but his theory was discounted by the later observation that 'war œdema' appeared to be produced by a diet deficient in fat and not in protein.

The fundamental step in our present knowledge of these diseases and the one on which all subsequent researches have been based was the observation of Eijkman that polyneuritis can be produced in fowls by feeding them on rice with all the pericarp removed by polishing, and that the occurrence of the disease can be prevented, or its cure after it has developed can be brought about, by the addition of rice polishings to the polished rice in the diet. Eijkman was followed by McCarrison and his associates, who produced pure polyneuritis and true beri-beri in pigeons by feeding them on polished rice. Soon after this Stanton, Fraser and Funk, and a little later Braddon, Vedder and Chamberlain brought forward satisfactory evidence that the artificially-produced disease of birds and beri-beri in human beings were essentially the same, and that one cause, at least, of both conditions was the eating of highly polished rice deprived of its pericarp. It was then discovered that the pericarp of rice contained a special factor, now known as vitamin B, and that the absence of this substance which is removed when rice is too highly polished was the cause of the disease. This vitamin is present in many other foods as well as the pericarp of rice, so it is only among races which depend chiefly on rice for their food that the amount of polishing to which it is subjected becomes a matter of importance.

Not long after the above facts appeared to have been firmly established a doubt arose as to their being the complete explanation of the problem, because it was noticed that some rice-eating peoples still developed œdema and its sequelæ at certain seasons of the year, even when they were eating rice with sufficient pericarp adhering to it to prevent beri-beri. Accordingly attention was now directed towards the possibility of rice being harmful in other ways than by deficiency of pericarp alone.

Arguing from the clinical manifestations of epidemic dropsy, which are more like those of a toxæmia than of a food deficiency, and from the fact that outbreaks are often of an explosive

nature such as would be unlikely in food deficiency, Bernard of Saigon, Conton, Leporini, and Wydooghe have formulated the theory that the disease is an intoxication or toxi-infection due to the action of bacteria on the intestinal contents. Megaw, Acton and Chopra, working in the Calcutta School of Tropical Medicine, have had a unique opportunity of studying the epidemics which have occurred from time to time in Calcutta and its adjoining suburb, Howrah, and they consider that epidemic dropsy and some of the conditions occurring in other countries hitherto described as beri-beri are different clinical aspects of a toxic syndrome caused by the ingestion of poisonous bases formed in rice under improper conditions of storage. By studying all the different grades of rice consumed in the localities affected, Acton and Chopra were able to show that the rice grains were definitely diseased and that they were attacked by a spore-forming proteolytic bacterium of the *B. vulgatus* group, which gives rise to poisonous bases from decomposition of the grain. Evidence has also been adduced that these bacteria may act on different grades of rice and produce different amounts of the toxins which cause neuritis and œdema. The views of the Calcutta School have not been universally accepted and criticisms have been levelled at it from time to time. Striking confirmation of the Calcutta

work has recently been provided, however, in another distant part of the world, and elsewhere in this issue will be found a very full abstract of a valuable report from Sierra Leone. Here, Dr. Burnett, following the lines of investigation suggested by the work done in Calcutta, has provided overwhelming proof that epidemic dropsy is a common condition in that colony and that it is caused by the consumption of old and badly-stored rice.

Whatever may be the real position with regard to the identity of the two diseases, beri-beri and epidemic dropsy, there is little doubt that rice dietary plays a very important part in their ætiologies. It is important therefore for nations whose staple food is rice to realize this fact and to adopt stringent preventive measures. These diseases are so serious, they are responsible for such an immense amount of mortality and morbidity, and their prevention appears to be such a simple matter, that Governments of the countries affected might well consider the advisability of formulating regulations for ensuring the proper storing of rice, and for restricting the sale of diseased grain. Such measures, if effectively carried out, would probably stamp out this disease in a very short time, and the drafting and enforcement of a code of regulations on these lines offers a great opportunity for a large scale demonstration of the value of preventive medicine.

Special Article

THE DIAGNOSIS OF THE CLINICAL TYPES OF ASTHMA AND THEIR CAUSATION

By HUGH W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Director, School of Tropical Medicine and Hygiene
and

DHARMENDRA, M.B., B.S.

Assistant Research Worker, School of Tropical Medicine and Hygiene

WE have divided our cases of asthma into two main groups: (a) cases in which the attacks are secondary to infections of the respiratory tract, i.e., nose, throat and bronchi, and (b) allergic cases. We are of the opinion that a consideration of the personal and family history together with the results of the blood examination will usually enable a case of asthma to be classified into one of these two main groups. An examination of the nose and paranasal sinuses, a skiagram of the chest, von Pirquet's test, and sputum analysis will confirm the diagnosis in the cases in which the attacks are secondary to infection of the respiratory tract. The dermal tests and examination of the

stools will help in the diagnosis of the allergic cases.

In previous papers (1933) we discussed the value of the Arneith count, the eosinophile count and the presence of Gram-negative bacilli in the sputum in differentiating one group from another. An analysis of one hundred and fifty cases has also been published; in this paper we have summarized the procedure which is followed when a case of asthma is admitted into hospital.

1. A history of the case is taken and the following points are carefully inquired into:

(a) A history of inheritance. This is commonly found in the allergic cases and rarely in the bronchial cases.

(b) The pre-asthmatic state. A history of having suffered previously from pneumonia, chronic bronchitis, or pleurisy is very suggestive of the bronchial type, while a history of a previous attack of dysentery or of urticaria is rather suggestive of the allergic type.

(c) Age of onset, the season of incidence and the association of the attacks with eating at a certain place or of a particular food. These are all important points; a history of the disease starting after thirty years of age with attacks

coming on during the winter or rainy season, or being worse at these seasons, is characteristic of bronchial cases. In these cases there is no association of the attack with any place or food. The allergic cases usually start early in life, have no seasonal variation, and the attacks may show an association with some place or food.

2. Examination of the blood. A total leucocyte count and a differential count is done and the total number of eosinophiles per cubic millimetre of blood is calculated. An Arneth count is done along with the differential count:

(a) The total number of leucocytes is not a reliable guide because various diseases in the tropics, such as malaria and kala-azar, lower the count. A high count is suggestive of sepsis and is found in bronchial cases, but when the high count is due to an increase in the number of eosinophiles it is found in the allergic and the Gram-negative-bacilli cases.

(b) The number of eosinophiles. Sometimes the results are difficult to interpret because other causes, such as kala-azar or malaria, depress the bone marrow function. A point to realize is that the results expressed as percentages of eosinophiles are not of much value, because a 5 per cent eosinophilia with a total count of 5,000 leucocytes only means 250 eosinophiles per c.mm., whereas with a count of 20,000 it means 1,000 eosinophiles per cubic millimetre. We now express our results in terms of total eosinophiles per cubic millimetre of the blood. Roughly, an eosinophile count of over 1,000 per cubic millimetre is suggestive of allergy but it is also seen in the Gram-negative-bacilli cases.

(c) The Arneth count: The significance of the Arneth count has been discussed recently by the writers (1933). The points of importance are briefly summarized below:—

In bronchial cases where sepsis is present there is an increased demand on the bone marrow so that young forms are thrown into the circulation at a greater speed than normally. The result of this enhanced supply is that cells with one- or two-lobed nuclei are found in greater numbers than normal—this is spoken of as a shift to the left in the Arneth count. When the Arneth index, which is the sum of the cells with one- and two-lobed nuclei and half the cells with three-lobed nuclei, is above 70, we consider it suggestive of the bronchial group. In the allergic cases there is no sepsis and hence no demand on the bone marrow for the increased production of the polymorphonuclear cells, so that the Arneth index is more or less normal, hence when the Arneth index is below 70 we regard it as suggestive of allergy. It is to be noted that in allergic cases with leucocytosis, although the bone marrow is active, there is no left-handed shift in the Arneth count because the increase in the number of the leucocytes is due to an increase in the number of eosinophiles and not of the polymorphonuclear cells. Thus we see that the combined readings of the Arneth index and the eosinophile count can be divided into four groups (see table):

(a) An Arneth index below 70 and an eosinophile count below 1,000 per cubic millimetre of blood. This group usually contains those allergic cases which have a low eosinophile count.

(b) An Arneth index below 70 and an eosinophile count above 1,000 per cubic millimetre of blood. This

group contains most of the allergic cases and some of the Gram-negative-bacilli cases.

(c) An Arneth index of above 70 and an eosinophile count of below 1,000. This group contains most of the bronchial cases.

ARNETH INDEX

Eosinophiles under	60- below	61-65	66-70	71-75	76-80	81-85	86-90	Above 90
250			2	1	6	5	2	1
500			3	8	3	3	2	
750		1	4	2	1	2	1	1
1,000	1	1	2	5	2	3	4	1
1,500					1			
2,000		1	1	2	1		1	1
3,000	1	1		1	1			
4,000		1			1	1	1	1
5,000	1	1		1		1		
6,000				2	1	1	1	
7,000	1	1					2	
8,000		1	1					
9,000	1		1					
10,000		1		1			2	
11,000					1			
12,000	1		1					
13,000			1					
15,000				1				
16,000			1					1
18,000								
25,000						1		
34,000		1						

The table shows the distribution of the various clinical types of asthma according to their Arneth index and eosinophile count.

Allergic cases are shown in heavy type, Bronchial cases in fine type and Gram-negative-bacilli cases in outlined type.

(d) An Arneth index of above 70 and an eosinophile count of above 1,000. This group contains most of the mixed bronchial and allergic and the Gram-negative-bacilli cases.

Inversely this may be expressed as follows:—

(a) The bronchial cases usually have an Arneth index above 70 and an eosinophile count below 1,000.

(b) The mixed bronchial and allergic cases have an Arneth index above 70 usually with an eosinophile count of above 1,000.

(c) The Gram-negative-bacilli cases usually have an Arneth index above 70 with an eosinophile count of above 1,000.

(d) In the allergic cases the Arneth index is almost always below 70 and is usually associated with an eosinophilia of above 1,000, but the eosinophile count may be low in some cases when the total count is low.

3. *Analysis of the sputum.*—A smear made from the purulent portion of the sputum usually shows the common micro-organisms—pneumococci, streptococci and *Micrococcus catarrhalis*. In 18 per cent of our cases, in addition to these micro-organisms, we found Gram-negative bacilli resembling *Klebsiella pneumoniae* (Friedlander's bacillus). We isolated the last-named organisms from the cultures made from sputa; fourteen out of the fifteen strains studied were non-lactose fermenters, they fermented glucose, maltose, saccharose and usually mannite with the production of acid only. The organisms were very pleomorphic; in cultures coccid and long filamentous forms were seen. No capsule was demonstrated in any instance and the organisms were non-pathogenic to mice, thus differing from *Klebsiella pneumoniae* which they resemble superficially. Out of the fifteen strains studied thirteen belonged to the genus *Eberthella*. In its specific characters the organism is nearest to *Eberthella phaffi*, the causative organism of fowl typhoid, being non-motile, a non-lactose and non-dulcitate fermenter, forming acid in glucose, saccharose and usually in mannite and producing no change in litmus milk and not pathogenic to laboratory animals. Special significance has been attached to the presence of these bacilli in the sputum. Knott and Oriel (1930) obtained histamine-like effects from extracts of various asthmatic sputa. Referring back to the bacteriology of these particular sputa, they found that many showed numerous Gram-negative bacilli in the bronchial plugs. The broth culture of these bacilli has a histamine-like effect similar to that obtained from the sputum. They think that the histamine-like substance demonstrable in the plugs has arisen as a result of the growth of these bacilli within the small bronchial tubes. Oriel (1932) considers that the local production of histamine in the bronchi, in addition to causing contraction of the plain muscle surrounding the bronchi, would also tend to increase the permeability of the epithelium lining the bronchioles, and facilitate the entrance of foreign proteins and possibly of bacteria. We have not succeeded in demonstrating any histamine-like effect in cultures of the strains of the Gram-negative bacilli studied by us. All we can say at present is that the Gram-negative-bacilli cases constitute a clinical group characterized by a high blood eosinophilia and the presence of

pleomorphic Gram-negative bacilli in smears and cultures of the sputum. The benefit in these cases derived from vaccines made from these bacilli is the same as in the other bronchial cases.

We have not found the presence or absence of eosinophiles in the sputum of any diagnostic value. There was no correlation between the sputum eosinophilia and the blood eosinophilia. Out of the total number only 36 cases, i.e., a fourth of the total, had eosinophiles in the sputum. The cases with the Gram-negative-bacillus infection had a higher incidence of sputum eosinophilia than other cases.

4. *The therapeutic test.*—During the attack of asthma, the effects of atropine, aspirin and adrenalin are tried in turn, beginning with atropine, then trying aspirin and after that adrenalin. In some severe cases none of these three drugs gives any relief to the patient and we have to give morphine-atropine injections. A subcutaneous injection of 1/150th grain of atropine sulphate is given at the onset of the attack. Atropine paralyses the vagal nerve-endings in the bronchi, and if the attack is due to broncho-constriction from reflex stimulation of the vagus the injection will relieve the patient. On the other hand if the attack is due to direct chemical stimulation of the bronchial muscles it will have no effect on the attack. Gillespie (1931) by using the method of McDowall and Thornton for recording the movements of the isolated bronchi has shown that the bronchial muscles contract with pilocarpine injection and that a small dose of atropine immediately after this produces complete dilatation; a second dose of pilocarpine then produces no result, but a very small dose of histamine still causes the muscle to contract. Aspirin is given in the form of an A. P. C. powder (aspirin grs. v, phenacetin grs. iii and caffeine citrate grs. iii), and in the bronchial cases we have found it a very effective drug in relieving the spasm. In cases where the broncho-constriction is due to direct chemical stimulation (the allergic cases), the drug has no effect. Clement Francis (1929), discussing the prognosis of operations for removal of nasal polypi in cases of asthma, comes to the conclusion that the removal of polypi will benefit the asthma only if the patient can take aspirin. Probably in these cases the attacks of asthma are due to a reflex irritation from the polypi while in the unrelieved cases the polypus is only a coexisting factor and has nothing to do with the attacks of asthma which are due to some direct chemical stimulation of the bronchial muscle. Van Leeuwen (1931) reporting on the clinical treatment of 1,000 asthmatic patients in allergen-proof chambers states that 10 per cent of his cases were hypersensitive to aspirin and these patients were rarely benefited by residence in these chambers.

Adrenalin.—0.3 to 0.5 c.cm. of adrenalin hydrochloride (1 in 1,000 solution) is injected subcutaneously at the onset of the disease. We have seen that allergic cases are benefited by this injection more than bronchial cases. Adrenalin has no action on the vagus nerve-endings and acts best when the broncho-spasm is due to direct chemical stimulation. Therefore bronchial cases are benefited most with aspirin and the allergic cases most with adrenalin. This forms a good therapeutic test for differentiating these two types of cases.

We next confirm our diagnosis. In the cases due to infection in the respiratory tract we examine the nose and the para-nasal sinuses, try the von Pirquet's test and take a skiagram of the chest. The von Pirquet's test and an x-ray picture are of value in excluding tuberculous lesions of the lung. In our series of 106 bronchial and Gram-negative cases there was radiological evidence of tuberculosis in 18 cases, of these 13 had old healed lesions and 5 active disease. All the bronchial and the Gram-negative-bacilli cases showed enlarged hilus glands and increased fibrosis. The von Pirquet's test was positive in more than half the bronchial and Gram-negative-bacilli cases; a negative test is of definite value in excluding tuberculosis whilst a positive result does not always mean an active lesion; it may be due to an old healed focus.

The diagnosis in the allergic cases is confirmed by the examination of the stools and the results of the dermal tests.

Examination of the stools.—The allergic cases secondary to gut infection may show *Entamoeba histolytica* or the presence of the ova of helminths. The McConkey neutral-red lactose agar plate may show various non-lactose fermenting bacilli suggesting the presence of post-dysenteric lesions. These findings are rather important from the treatment point of view. Cases of gut origin are treated with emetine, carbon tetrachloride or an autogenous vaccine prepared from the pathogenic organisms isolated from the stools, the form of treatment depending on the diagnosis made from stool examination. In the ordinary way these infections do not cause asthma, but there may be a lowering of the defence mechanism of the liver from hepatitis caused by amoebic or some other infection. We are at present investigating the part played by the liver and the endocrine defence mechanism in producing these allergic cases which in India differ so markedly from European cases of the same type.

The dermal tests are of value in the following types :—

(1) When the respiratory mucous membrane is locally sensitive to specific dust, as in jute-mill workers. In 16 cases of asthma tested 10 gave a positive reaction between 1 in 10,000 and 1 in 1,000,000 dilution. Three only reacted at

a dilution of 1 in 100, but out of five controls only one reacted at 1 in 10,000 dilution.

(2) Cases which are sensitive to animal emanations.

(3) Cases in which a single rare food is responsible for the attacks.

In allergic cases dependent on some pathological condition of the gut, dermal tests are of no value, the tests are either totally negative or all the foods tested give a positive result.

Therefore we have discontinued making the dermal test as a routine and only use it when the history is suggestive of some animal emanation or of a particular food being responsible for the attacks.

The dermal tests are usually done on the forearm. The forearm is carefully cleansed with alcohol, and scratches are made on it transversely to the long axis of the arm. The scratches are only about $\frac{1}{4}$ th of an inch in length and they are made without drawing blood. One spare scratch is made to serve as the control. A drop of N/10 sodium hydroxide solution is put on each scratch and the substances to be tested are rubbed into them, one substance into each scratch, the control scratch receives nothing but sodium hydroxide. After 15 to 20 minutes the test fluid is wiped away and the results are read by comparing the site of each scratch with the control. A positive result is denoted by the appearance of an urticarial wheal at the site of the scratch. The materials for testing can be purchased ready-made from the market or they can be manufactured in the laboratory. The supernatant fluid obtained by macerating a small amount of the substance in a few drops of N/10 sodium hydroxide solution may be used for the test, but a better way of preparing an extract for dermal tests is to extract it with Coca's fluid. Coca's fluid is made by dissolving sodium chloride 10 gms., sodium bicarbonate 16.8 gms., and carbolic acid 8 gms. in two litres of distilled water. Before extracting house dust it should be washed in ether to remove the fat and then a 1 per cent extract made in this fluid. The extract should be filtered through a porcelain filter and the filtrate should be tested for sterility (aerobically and anaerobically) before it is used for the test. The test should be performed with very weak dilutions to avoid undesirable effects; it is best to commence testing with a one in a million dilution.

We can define our two groups:

(a) Cases in which the attacks are secondary to infection or disease of the respiratory tract, i.e., nose, throat, trachea and bronchi. This group includes the majority of cases amongst Indians. In our series of 150 cases this group included 70 per cent of them and they can be subdivided into

(i) *Nasal reflex*.—In this type the total leucocyte count is more or less normal, there is

no eosinophilia, and the Arneth count is normal. The cases that respond favourably to aspirin will be benefited by a nasal operation. In such cases an examination of the nose and para-nasal sinuses is carried out.

(ii) Cases in which the attacks are due to pressure of the enlarged hilus glands on the vagus nerve. In such cases there is no increase in the number of total leucocytes or eosinophiles and the Arneth count is more or less normal. The x-ray picture will show enlarged hilus glands.

(iii) Bronchial cases due to infection in the bronchi. These cases are subdivided into two groups :

(1) Gram-negative-bacilli cases. The total leucocyte count is high, there is an increased eosinophilia and a shift in the Arneth count to the left. A smear of the sputum shows the presence of Gram-negative bacilli resembling the pneumo-bacillus. The sputum is cultured and non-motile bacilli belonging to the Eberthella group are isolated. A vaccine is made from these organisms and it is used for treatment.

(2) Bronchial cases in which the infection is due to the ordinary organisms causing bronchitis. The total leucocyte count may be high or low, and there is no eosinophilia but there is a marked shift in the Arneth count to the left. In such cases cultures from the sputum are made to get the strains for preparation of an autovaccine. An x-ray examination of the chest and a von Pirquet's test are done to exclude tuberculous cases.

(b) *The allergic cases.*—There is usually a high leucocyte count and a high eosinophilia and no shift in the Arneth count. These cases may be divided into three groups :

(i) Local allergy of the mucous membrane to foreign substances such as dust. These cases may be congenital or may be acquired as a result of the previous disease of the bronchi. The congenital cases are rare amongst Indians but common amongst Europeans. In India the condition is more often acquired as the result of previous bronchitis. This type is common amongst jute and textile workers and in certain occupations where there is a large amount of dust in the atmosphere. Dermal tests are of value in diagnosing these cases. And they can be treated with extracts made from the specific dust. The treatment is carried out by giving graduated doses of the sterile dust extract.

(ii) Hereditary allergy, i.e., susceptibility to animal emanations. These cases are rare in India. Dermal tests are of value in the diagnosis and the treatment consists in avoiding the excitant or in desensitizing against it.

(iii) Allergy due to internal toxins. This group can be subdivided into two types :

(1) Those due to some rare or common food or foods. Dermal tests are useful in the

diagnosis of these cases, but this type is rare amongst Indians.

(2) Those with allergic symptoms secondary to bowel diseases. These are common amongst Indians and the dermal tests are of no value because either they are all negative or all the foods tested give positive results.

It is interesting to note that the allergic conditions of the skin bear a close resemblance to the allergic conditions of the bronchi. Thus abnormal sensitiveness of the mucous membrane of the bronchi to foreign substances may be well compared to the condition of the skin known as dermatographia, when it is abnormally sensitive to external stimuli, such as scratching. Hypersensitiveness of the bronchial mucosa developing after some disease is comparable to dermatitis venenata which may develop after certain skin diseases. Allergic asthma due to internal toxins may be compared to urticaria which is an abnormal sensitiveness of the skin to internal toxins.

We have divided our cases into two groups—bronchial and allergic, but there are some which are a mixture of the two types. For example if a case starts with bronchial symptoms but later the mucous membrane of the bronchi becomes hypersensitive to dust, or other substance as a result of the disease, it will present a mixed blood-picture, high leucocytosis, high eosinophilia and a marked shift in the Arneth count to the left. Similarly in a case which starts as an abnormal sensitiveness of the mucous membrane to external stimuli, the repeated turgescence of the membrane and its lowered resistance leads to bacterial infection of the mucous membrane, and later the bronchial glands may become enlarged as a result of this infection.

AMALGAMATION OF THE ROSS INSTITUTE AND HOSPITAL FOR TROPICAL DISEASES WITH THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

We have received a memorandum by Sir C. C. MacLeod, Chairman of the Ross Institute, on the proposal to amalgamate the above institutions; this we understand has now been accepted.

This amalgamation cannot fail to be of advantage to research in tropical medicine in London, for in the first place it will mean a considerable economy in funds at a time when money is by no means plentiful and it also will mean an economy of effort because with two such institutions as the above working independently in the same locality there must have been a certain amount of overlapping. This will now be completely done away with as under the scheme of reorganization outlined in this memorandum the work of the two bodies will be altogether complementary.

The heads of departments of the Ross Institute are to be given departments in the London School and the department of tropical hygiene, which has been without a head since the death of Sir Andrew Balfour, will now be known as 'The Ross Institute of Tropical Hygiene' and it will be placed in charge of Sir Malcolm Watson.

The work that was being carried out in India under the auspices of the Ross Institute by Dr. G. C. Ramsay will be continued as heretofore.

SPECIAL COURSES IN THE STUDY OF MALARIA

We have received from the Director, League of Nations Health Organization, Eastern Bureau, notice of the first course in instruction in malaria under the direction of this body, which is to commence on 30th April, 1934, at Singapore. It is proposed to hold these courses every year and the duration of study is to be about thirty days at a cost of seventy-five Straits dollars. The laboratory and clinical course in Singapore will be followed by a month of practical training in anti-malarial work in the field in countries near Singapore where much valuable anti-malarial work is being carried on, and anti-malarial schemes on a large scale are available for demonstration.

The syllabus, of which we have received a copy, indicates that the scope of training is very wide and deals with all aspects of the problem, and if the course is carried out according to the lines laid down it cannot fail to be of the greatest value to those attending it.

Anyone requiring particulars of this course can obtain them from the Director, League of Nations Health Organization, Eastern Bureau, Singapore.

THE INTERNATIONAL ORGANIZATION OF CHEMICAL DOCUMENTATION

QUESTIONS concerning documentation have of late assumed more and more importance. Scientific and technical documents increase on all sides in such numbers that it becomes more and more difficult to gather useful material for the benefit of inquirers. There are many bodies that deal permanently with the registering, classing and diffusion of such documents. Now the co-ordination of the respective activities of these institutions on an international basis has become necessary in order to permit them to carry on their work efficiently.

As regards the province of chemistry a step was taken in 1932, in the scientific and technical sphere, by the entry into activity of the *International Office of Chemistry*, created by an international convention, and having its headquarters in Paris.

Its first act was the summoning of a conference of experts, which included the following: Messrs. *F. Donker Duvis*, Member of the Council of Patents, The Hague; *P. Dutoit*, Professor at the University of Lausanne; *P. Haber*, Director of the Kaiser-Wilhelm Institut für Physikalische Chemie und Electrochemie, Berlin; *E. Hauser*, Member of the Academy of Sciences, Madrid; *Ch. Maric*, Secretary General of the Comité International des Tables Annuelles de Constantes, Paris; *N. Parravano*, Member of the Academy of Italy, President of the Comitato Nazionale di Chimica, Rome; *G. Penny*, President of the Federation of Chemical Industries of Belgium, at Brussels; *J. C. Philip*, Professor at the Imperial College of Science and Technology, London.

The work of this conference of experts led to the adoption of a certain number of recommendations fixing the three principal tasks of the office:

I. To render accessible to all interested persons the already existing documentation, accumulated in the various centres, depots and collections.

II. To guide the chemical documentation which is in course of production, in such a way as to facilitate its registering, filing and diffusion, by methods found to be the best.

III. To ensure co-ordination between the documentation relative to chemistry and that concerning other scientific knowledge in the field of international documentation.

Thanks to these varied operations, the users of such documentation will find that all over the world a practical and rational organization of documentation in chemistry is being carried out systematically and progressively, liable to be more and more effectively adapted to their needs.

RAI SHAMBHU DAYAL SAHIB GOLD MEDAL

(1) A gold medal called the 'Rai Shambhu Dayal Sahib Gold Medal' will be presented for the best prize essay on a public health subject to be announced each year.

(2) The subject of the next essay is 'Ancient prejudices and customs which hamper public health work in these Provinces and remedies suggested to overcome them'.

(3) The competition will be open to the general public including the medical, and the public health workers, in the United Provinces.

(4) The essay is to be written in Hindi and should not exceed 3,000 words in length.

(5) Essays should reach the Medical Officer In-charge, Provincial Hygiene Institute, United Provinces, Lucknow, by 15th December, 1933.

(6) The name and address of the competitor must be distinctly written on each essay submitted and the envelope should have the words 'Prize Essay' in the top left hand corner.

(7) The Director of Public Health, United Provinces, shall judge the merit of the essay and his decision with regard to the award of the medal shall be final.

(8) No correspondence will be entered into on the subject of the competition.

(9) No essay will be returned.

BOMBAY MEDICAL COUNCIL

THE following extract from the summary of the proceedings of the meeting of the Bombay Medical Council, held on the 4th September, 1933, has been forwarded to us for publication.

The Council proceeded to consider the conduct of Mr. Motiram T. Ramchandani in giving an incorrect medical certificate against whom the Sessions Judge, Hardoi (U. P.), passed certain remarks, and as requested by the practitioner adjourned the formal inquiry into the case till February 1934.

The Council considered the case of Mr. Wazir Singh who was convicted under section 354, I. P. C., by a law court in the Punjab and directed the Registrar to erase

the name of the practitioner from the Bombay Medical Register.

The Council proceeded to consider the conduct of Mr. N. K. Panse, I.C.P.S., against whom the Assistant Sessions Judge, Sholapur, had made remarks for giving an incorrect medical certificate. After considering the reply from Mr. Panse, the Council adjourned the case till February 1934.

The Council next proceeded to consider a reference from Government forwarding the application from Mr. T. T. Shahani for permission to be registered under section 7 (3) of the Bombay Medical Act, 1922, and resolved to recommend to Government that the practitioner be given permission to be registered.

The Council considered a similar reference on an application from Mr. U. L. Bhatt and resolved that Government be informed that the practitioner may not be given permission to be registered.

The Council resolved to make a reference to Government to give certain concessions in payment of travelling allowance to members from Sind attending the Council Meetings.

The Council considered a proposal to the effect that registered medical practitioners should not associate themselves with foreign medical men who are not registered and who advertise themselves and hail their advent in lay papers, and that a registered medical practitioner should not advertise his subject and substance of lectures in lay papers, and to amend the Code of Medical Ethics to the effect that a registered practitioner should not give his or her name or surname to an institution run by him or her unless it is founded purely for charitable purpose and resolved that necessary additions and alterations be made to the Code of Ethics published for the information of registered medical practitioners.

FIFTY YEARS AGO

(From the *Indian Medical Gazette*, November, 1883, Vol. XVIII, pp. 321, 322 and 323) .

THE 'BLACK DISEASE' OF THE GARO HILLS

We are indebted to Deputy Surgeon-General J. J. Clarke, M.D., Sanitary Commissioner of Assam, for a clear though brief description of a black fever which has been known to prevail in the Garo Hills for some time past. How long it has been there it is impossible to say. Attention was first drawn to it in the year 1869, and the two features which attracted the notice of the civil officers who reported on it, were the blackness of the skin of its victims, and the great mortality caused by the disease. Numerous villages in the Garo Hills district were 'almost depopulated by the plague'. Inquiries instituted by Mr. McNaught, Civil Medical Officer of Tura, have enabled Dr. Clarke to furnish a tolerably complete account of the symptoms of the malady and to indicate the circumstances, topographical and hygienic, under which it originates and flourishes. The disease may be described as a fever resulting in a profound and fatal cachexia.

* * * * *

The disease is most intense where the low densely-wooded Garo Hills join on to the low-lying Central Assam plain, a position *par excellence* the most favourable for malarial developments. It extends also to some distance into the hill country, where the lower outer ranges are overtopped by higher interior ranges, but among these higher hills the disease is almost unknown. The villages where it is prevalent are often built in the midst of dense jungle, which the sun cannot penetrate, and where the air cannot have free access. The habitual Garo practice of annually clearing thick jungle and breaking up the ground, thus vivifying into new intensity *pro tempore* the malarious influences tends further to increase the disease. It occurs severely in the lowlands surrounding the base of the Garo Hills. This tract is only partially cultivated, swampy, totally undrained, and chiefly covered by reed or grass jungle.

We have strong support in assigning a malarial origin to this malady. The regions where it prevails could not have been better selected were malaria cultivation desired. Wells are unknown, and the water supply is mostly derived from stagnant valley water or muddy pools, which must be living masses of bacilli and infusorians adjuvant factors in the ætiology may be recognized in the facts that the habits of the Gáros are exceedingly filthy, that their food is often deficient in quantity as well as in quality, and that the poorer classes chiefly suffer. The Gáros give definite accounts of the invasion of their villages by this endemic at periods varying from 3 to 30 years previously. They firmly believe in its infectiousness, and will not communicate or associate with infected individuals. No evidence has been adduced by Europeans to prove this belief, and it is probably quite unfounded.

The question of occasional infectiousness of forms of disease usually endemic and non-infectious is an extremely difficult one, and demands inquiry of a very searching and discriminating kind. It is not uncommon for fevers of undoubtedly malarious type to assume an epidemic aspect. Such was the case with the so-called 'Burdwan fever' which caused so much sickness and mortality in Burdwan and the adjacent districts 10 years ago, and in reading of the terrible outbreaks of fever which sometimes prevail in towns and jails up-country, it is extremely difficult, apart from the question of type, to decide whether the element of contagion is or is not a factor of causation. Even as regards such a disease as pneumonia the same doubt arises, and strong reasons have been urged in favour of the view that a certain intensity of type may determine communicability.

In all cases where the area of prevalence of a disease can be defined with reasonable distinctness, and where certain conditions, topographical or hygienic, can be pointed out, as peculiar to that area, the doctrine of infectiousness must be advanced with great hesitation, and the present seems to be a case in point. A dank terrai land inhabited by a population eminently wanting in all civilized sense of comfort and cleanliness, is eminently favourable to the origin and prevalence of malarious disease, and the lesson which the interesting observations recorded by Dr. Clarke proclaim, is simply an echo of that which the history of pestilential disease has often taught, namely, that the 'black' forms of disease are due to neglect of the laws of hygiene. The suggestions, which he has formulated for the prevention of this plague, are framed in conformity with this principle, and appear to us to be thoroughly suitable and sound. They are mainly directed towards clearing and draining the sites of villages and houses, and improving the food and water of the people. These are fundamental requirements, and combined with a proper system of conservancy, we have no doubt that their realization would effect a great abatement of this *kala-azar* in respect both of prevalence and virulence.

Current Topics

A Note on Vitamins in Practical Experience

By LESLIE J. HARRIS, D.Sc., Ph.D.

(From the *British Medical Journal*, 5th August, 1933, p. 231)

IN my paper to the Section of Diseases of Children at the Dublin Meeting of the British Medical Association, dealing with the practical significance of vitamins in day to day clinical experience, I have confined my attention largely to the anti-rickets vitamin D, which, of course, in this country, is the factor of pre-eminent importance. A list of conclusions is, however, included relating to vitamins A, B, and C and certain other

practical issues; and it is the purpose of the present brief notes to summarize the evidence on which these conclusions are based.

VITAMIN A NOT A GENERAL ANTI-INFECTION AGENT

Week by week advertisers' announcements are sent to us all by post, or appear in the journals, which rather convey the impression that vitamin A builds up the general resistance to infection and is of value in the treatment of toxemias and infectious diseases of all kinds. This is claiming far too much. Vitamin A is anti-infective in only a limited way. As I have shown, in collaboration with J. R. M. Innes, the local infections to which vitamin A deficiency gives rise are of a quite special type, being caused by structural breakdown of membranes. There is no change in the general immunity. These scattered, localized infections are restricted in origin to the abnormal membrane, and are set up by chance micro-organisms which would normally prove to be non-pathogenic. There is no reason to suppose that vitamin A could exert any direct bactericidal or similar effect when given in definite cases of infectious diseases and septicaemias caused by the invasion of specific virulent micro-organisms. Dr. Griffith and I showed, for example, that vitamin A had no effect on the spread of experimental tuberculous disease. Again, our colleague Dr. Thomas Moore has found that in human beings dead from the most varied types of infectious diseases there may be abundant reserves of vitamin A in the body, so that little could have been gained by its administration in such cases, and it is obviously no longer possible to regard the vitamin as an anti-infective agent indiscriminate in its scope. The original observation which held out the hope of wide positive therapeutic uses for vitamin A was that of Mellanby and Green; it appeared to show that in puerperal septicemia the mortality was strikingly diminished as a result of vitamin A treatment. Mellanby suggested that many common infective conditions might be due to vitamin A deficiency, including the common cold, acute rheumatism, phthisis, bronchitis, pneumonia, middle-ear disease, ulcerations of mouth and eyes, and inflammations of nasal sinuses. However, later clinical investigations by many workers have shown that vitamin A therapy has failed to have any effect as a prophylactic in respiratory diseases, in the common cold in infants, on the incidence of common infections generally, or in the treatment of pneumonia. As has been agreed by Mellanby, a difficulty in interpreting his original, apparently favourable, results in puerperal septicemia is the great natural variation in virulence from case to case. Ellison claims to have reduced the mortality rate in measles in young children by treatment with vitamins A and D. In a group of 300 cases so treated there were eleven deaths, and in a similar control group of 300 given no extra vitamins twenty-six deaths. Further statistical evidence will, of course, be needed before the claim can be regarded as definitely established. Ellison points out how there often occurs after severe measles a metaplasia in the respiratory tract resembling that of vitamin A deficiency, and this might be regarded as providing a rationale for the treatment. We may certainly admit that it is in young children—the class studied by Ellison—that any liability to shortage of vitamin A seems most likely to occur (see below).

VITAMIN A REQUIREMENTS

Although we are satisfied that vitamin A is of no value as a general anti-infective agent for indiscriminate use in treating all kinds of infectious diseases it is still important to ensure that enough of the vitamin is given in the diet, as there is full evidence to show that a lack must lead to specific ill effects (including xerophthalmia, or night-blindness, often accompanied by tendency to respiratory infection. In many parts of the world avitaminosis A is widespread, while it will come as a surprise to most to hear that in this country it is not quite unknown, no fewer than seventeen cases

of xerophthalmia being recorded in one year in a North of England hospital. A recent report from America gives details of thirteen such cases in under-nourished children. As to the more difficult question of partial lack of this vitamin (hypovitaminosis) it is hard to speak with any certainty. The results of Moore for the British Isles and of Wolff for the Netherlands suggest that about 16 per cent of the population might perhaps be considered to have 'sub-normal' reserves, but it is difficult to know how to fix the limit for normality. The reserves found vary immensely from one individual to another.

Work by my colleague Dr. W. J. Dann, in particular, has shown that the young of the species receive a surprisingly limited amount of vitamin A *in utero* and in their mother's milk, so that the need for ample provision of this factor *especially at weaning* becomes all the more apparent. Vitamin A is found in most animal fats (except lard) and fish oils; but carotene, which is of equal biological value and is converted to vitamin A by the animal (as shown by Moore at Cambridge), is as readily accessible in green vegetables, carrots, etc. We may sum up the matter of vitamin A dosage by drawing a contrast between it and its fat-soluble companion D. Whereas with vitamin D no common food-stuff contains an abundance, so that supplementary dosing is an absolute essential if the deficiency (rickets) is to be averted, many common articles (any common greenstuffs) contain all that is needed of vitamin A, so that separate dosing cannot be regarded as being so imperative, but merely as an additional safeguard in cases of doubt.

VITAMINS B₁ AND B₂

Vitamin B₁ deficiency (beri-beri), including the infantile variety, is almost universal in certain parts of the globe, but there is little evidence of any serious lack of this vitamin in this country or in the U. S. A. True, the possibility of some partial want is suggested by experiments recently carried out in America, which showed apparently quite conclusively that when sources of extra vitamin B were added to the diet of large groups of infants the growth rate or weight curves, or both, were far ahead of those of the control groups. We must await further tests before dogmatic statements can be justified. Intestinal stasis and lack of alimentary tone is admittedly one effect of vitamin B deficiency, but in my opinion there is no compelling evidence for the widely advocated theory that the prevalence of constipation in this country is due to vitamin B shortage. Pellagra (vitamin B₂ deficiency) has an astonishingly high incidence in the U. S. A. (170,000 cases in 1917; 120,000 cases in 1927; mortality rate about 40 per cent), but it is not a disease of children, and is therefore outside the scope of our present discussion.

VITAMIN C

It is nowadays the recognized orthodox practice to give all bottle-fed infants fruit juice for the purpose of preventing Barlow's disease (infantile scurvy—that is, deficiency of vitamin C, recently identified with *hexuronic* or '*ascorbic*' acid). This is an essential procedure, as cow's milk is a rather poor source of vitamin C, and pasteurization may destroy what little there is—this, to a greater or less extent depends on the conditions of the pasteurization, the presence of copper particularly inactivating the vitamin. This question is of much current interest and importance in view of the proposed legalization of compulsory pasteurization—a process which, it may be noted in parenthesis, is of commercial benefit to the dairying interests, since pasteurized milk 'keeps' longer and can be sold when staler. We do not know at all accurately to what extent vitamin C underfeeding is current in this country; but the fact that definite outbreaks of scurvy tend to appear (as in Manchester, Glasgow, and Newcastle in 1917) whenever there is a failure in the potato crop suggests that many people must be near the borderline, and that they rely too exclusively on

the potato as their sole source of the vitamin. The consumption of other vegetables and salads and fruit should be encouraged: a useful 'rule' that has been advocated is to spend as much on fruit and vegetables as you do on meats and fish and, incidentally, the same sum again on *milk*. (Here, of course, we are speaking of children and adults, not young infants.) In Sweden Göthlin believes, from his tests on capillary strength, as measured by the liability to cutaneous hæmorrhage under given pressures applied to the skin, that 18 per cent of a group of country school children were suffering from hypovitaminosis C. E. W. Fish and I find that vitamin C deficiency in experimental animals leads not only to failure in function of odontoblasts (as had been previously observed), but also to faults in enamel formation of the type which precedes dental caries in man. It is quite likely that deficiency of vitamin C—no less than of vitamin D, which has been studied so fully by M. Mellanby—may often be a contributing cause of dental caries.

OTHER NUTRITIONAL FACTORS

I would not wish to close without making at least a cursory allusion to nutritional factors other than vitamins, lest I might seem to convey the impression that vitamins alone mattered. Among the most striking of recent work is that of Mackay, who has shown how surprisingly common is iron deficiency in infants, and has published a convincing account of the beneficial effects of its administration in such cases. The observations, too, of Corry Mann on the unique nutritional properties of milk for school children, work which has since been amply confirmed up and down the country, call for special mention.

THEORY AND PRACTICE

In conclusion, we must realize that our problem cannot be divorced from economic realities. Calculation shows that the cheapest diet for bare sustenance costs about 5s. to 7s. a week for an adult, or about 3s. to 4s. for a child. This figure assumes a knowledge of how to choose food to the best physiological advantage, and also the opportunity of purchasing it in the cheapest markets. Yet it has been shown that even this minimal sum is beyond the reach of many of the unemployed, whose income falls short of that amount after deducting only for rent, and making no provision whatsoever for such necessities as clothes, heating, etc. The fault here lies not with science, but largely in the malorganization of society, and sometimes too in a failure to apply or to realize the knowledge which science has already won. In America it has been found worth while to employ whole corps of 'nutritionists', whose function is to advise the public authorities as to nutritional conditions and local needs, and to instruct households on the outlay of their budgets.

Remarks on Essential Vascular Hypertension

By SIR HUMPHRY ROLLESTON, *Bart., A.C.N.O., R.C.B., M.D.*

(Abstracted from the *British Medical Journal*, 5th August, 1933, p. 223)

NATURE OF ESSENTIAL HYPERTENSION

ESSENTIAL HYPERTENSION may be briefly described as a persistently raised systolic and diastolic blood pressure not due to arterio-capillary, renal, cerebral, or other recognizable morbid change. It therefore resembles chronic splenic anaemia, in that many cases of undetermined aetiology are grouped under one descriptive term. It may however, cause, and be the antecedent stage of, cardiovascular changes, renal fibrosis, and their various results. There is good evidence that a raised blood pressure and renal disease can each cause the other, and that, in an early stage, the renal lesion wrought by hypertension is an arteriolar thickening and narrowing in an otherwise normal organ.

It has often been urged that high blood pressure is a compensatory adaptation to maintain an efficient circulation through the kidneys, brain and myocardium. Reid's observations on patients did not support this view as regards renal function. Experimentally increase of the intracranial pressure above that in the cerebral arteries produces anaemia of the brain, and thus calls forth, through the vasomotor centre, a general rise of the systemic arterial blood pressure. Starling suggested arteriolar proliferation in the vasomotor centre as the cause of hypertension. Bordley and Baker found a definite association between hypertension and arteriosclerosis in the medulla oblongata; out of twenty-four cases of generalized arteriosclerosis, fourteen with constantly raised blood pressure showed arteriolar changes in the medulla, whereas in the remaining ten cases with normal blood pressure the medulla was free from arteriolar changes. Cutler nor Tuthill could confirm this correlation. According to Evans, hypertension and the diffuse hyperplastic sclerosis of the arterioles are concomitant effects of the same cause. MacWilliam, after a full physiological discussion, concluded that the hypertensive impulse, however caused, emanates from the controlling vasomotor centre in the medulla. It has been suggested that the condition may depend on hypersensitiveness of the vasomotor centre, but as the result of experiments Kroetz contested this. Vasomotor instability is present in many cases of hypertension, but whether as the primary cause, as a concomitant reaction, or as a result is open to debate. It is conceivable that a metabolic poison selectively constricts the arterioles of the vasomotor centre, and that the resulting ischaemia stimulates pressor impulses.

That the peripheral obstruction responsible for high blood pressure is due to spasm and not to structural narrowing was rendered highly probable more than forty years ago by W. H. Broadbent's observation that vasodilators such as amyl nitrite produce a fall of pressure. Clinical observation proves that arteriosclerosis and high blood pressure, though often associated, occur independently of each other; there is indeed much more evidence that long-continued hypertension is responsible for degenerative arterial changes than that ordinary arteriosclerosis raises the blood pressure. The site of the peripheral obstruction in essential hypertension, whether in the arterioles, as is suggested by their visible constriction in the retina, in the capillaries, or in both, is an open question, and it is quite conceivable that it varies.

The constant normal fluctuations in the capillary bed, however, render it doubtful if the capillary pressure estimated in the skin represents that in the extensive splanchnic and other deep areas of the body. Kylin stated that the capillary pressure is raised in glomerulonephritis, in which there is widespread capillary change, but is normal in essential hypertension; Boas and Mufson, however, found the capillary pressure high in seventeen and normal or low in twenty-eight out of forty-five cases of essential hypertension.

A division has been made into benign and malignant hypertension. But the malignant form is apparently a complication with diffuse change in the arterioles, which in some rare recorded cases has resembled that in periarteritis nodosa. It mainly occurs in the comparatively young, in the fourth decade, and runs a rapid course with very high blood pressure, acute functional failure of the brain, myocardium, and kidneys, death being often due to uræmia. Fahr described the renal changes as malignant nephrosclerosis, and Boyd as resembling those in the 'flea-bitten' kidney due to the embolic focal glomerulo-nephritis in subacute bacterial endocarditis with necrotic changes due to ischaemia. It is therefore clear that 'malignant hypertension' differs from uncomplicated essential hypertension.

ÆTIOLOGY

If it be accepted that essential hypertension proceeds, and may eventually be responsible for, arteriosclerosis and chronic renal sclerosis and not vice versa,

what are its causes? A persistently raised blood pressure is a retention, and it is no longer necessary, in obedience to the law that there is 'but one cause for one effect', to explain all cases of essential hypertension by a single and therefore specific factor such as renal inadequacy, endocrine disorders, mental worry, or errors of metabolism. While it is safest to take an agnostic attitude about the cause, many hypotheses have been put forward.

Heredity.—Heredity has been rightly considered to be a disposing factor. It is shown to be so by family records, from a study of which Weitz concluded that 'genuine or vascular' hypertension is a constitutional disease with dominant Mendelian characters. George Draper has tabulated the anthropometric characters of those prone to become the subjects of hypertension, and Major recently illustrated the influence of heredity by the freedom from high blood pressure of the pure-bred Chinese, with their Oriental calm, in the past. In the symposium, *Arteriosclerosis* (1933), edited by Cowdry, both Lange and G. D. Williams throw doubt on the influence of heredity in the majority of cases.

Endocrine disorders

In addition to the nervous mechanism of the sympathetic and parasympathetic, chemical factors play an important part in the control of the circulation, the two mechanisms being closely related. The chemical messengers or hormones exerting a pressor effect are adrenaline and vasopressin (posterior lobe of the pituitary).

An excessive secretion of adrenaline (hyper-nephrism) was suggested as a cause of hypertension in 1904 by Vaquez, Josué, and others; but, as evidence of adrenal overactivity, stress was laid on hyperplasia of the cortex, which may well have been a secondary lipid storage, and as numerous observers failed to find a greater pressor effect from the blood of hypertensive than from the blood of normal subjects, the view failed to carry conviction. It has been revived, however, by Vaquez, with very definite reference to overactivity of the chromaffin system, by Paul, and by Goldzieher who has described hyperplasia of the adrenal medulla. So far, however, the presence of adrenaline in the blood of subjects with essential hypertension has not been established.

Primary adrenal tumours have, in rather exceptional instances, been associated with hypertension, and a brief reference to this subject has some bearing on the hypothesis that hyper-adrenæmia is responsible for essential hypertension. Of the various forms of primary adrenal tumours some, especially the undifferentiated tumours (neuroblastomas) of the medulla, are not associated with a raised pressure, whereas the subjects of well-differentiated chromaffin tumours may experience paroxysmal crises of high blood pressure, a condition distinct from essential hypertension. Some cortical tumours, contrary to what would logically be anticipated, have been associated with persistently raised blood pressure.

Primary tumours of mature chromaffin cells (phaeochromocytomas when arising from the adrenal medulla, paragangliomas when derived from chromaffin cells elsewhere) are rare; Rabin collected thirty cases, in ten of which the blood pressure was raised. Marcel Labbé recorded a case with paroxysmal hypertension, and later collected eight of a similar character. Adrenaline has been found in these tumours. These crises, between which the blood pressure may be normal, follow slight exertion, or occur without obvious cause; the blood pressure may rise to 300 mm. Hg., and pulmonary oedema may occur. They may perhaps be regarded as the pathological equivalent of the events described in Cannon's 'emergency hypothesis'—namely, discharge into the circulation of adrenaline in excessive amounts in response to emotions such as fear. This form of paroxysmal arterial hypertension varies much in degree and duration, the latter from seconds to days (Castex). The attacks have been regarded as much

the same as those of Nothnagel's angina pectoris vasomotoria and those due to intravenous injection of adrenaline. Freedom from further crises has followed removal of the tumour.

Primary tumours of the cortex have been associated with a continuously raised blood pressure in rather exceptional cases, which have been recorded and collected by Volhard, Langeron, and Lohéac. The cortical tumours may be bilateral. It is not known if these cortical tumours are constantly derived from any one of the usually described three zones of the cortex. Cushing, however, brought forward evidence that some at least of the reported cases of cortico-adrenal hypertension are examples of basophil adenoma of the anterior lobe of the pituitary.

Deficiency of hypotensive bodies in the circulation is, as pointed out by MacWilliam, a possible cause of hypertension. The extracts of many organs and tissues—some, such as histamine, choline, acetylcholine, and adenosine, known, others, from the liver and brain, unidentified—exert a depressor influence on blood pressure. But apart from these reference may be made to the hormone vagotonine, recently isolated from the pancreas by Santenise; it is separable from insulin, increases the reflex excitability of the vagus and parasympathetic, and exerts a depressor influence different from that of choline, histamine, adenosine, peptone, and from the other hypotensive bodies extracted from the pancreas by Livon, P. Gley and Kistlinios, and Frey and Krant ('kallikrein'). Whereas the latter extracts produce an immediate fall of blood pressure which may be followed by a rise, the hypotensive effect of intravenous or hypodermic injection of vagotonine is delayed, slowly progressive, prolonged, and never followed by a hypertensive reaction. An intravenous injection of vagotonine before one of adrenaline inhibits the secretion and impairs the activity rather than directly neutralizes the action of adrenaline.

That vagotonine may play a part in controlling the rise of blood pressure and its absence in some cases account for hypertension is perhaps supported by the observation that in uncomplicated hypertension the tonus of the sympathetic nervous system was increased and that of the parasympathetic diminished, as compared with normal subjects; and also by the frequency of a low sugar-tolerance in hypertensive subjects, for Santenise found that vagotonine has a hypoglycæmic effect less rapid in onset, but more prolonged, than that of insulin. Abrami, Santenise, and Bernal have treated eighty patients with high blood pressure of various kinds by vagotonine, usually by hypodermic injection: thirty of these were permanently better after a series of injections, the best results being obtained in those with paroxysmal crises of hypertension: a number of patients did not respond to vagotonine. These results, taken in conjunction with the paroxysmal crises of high blood pressure in patients with chromaffin-celled tumours of the adrenals, lend support to the view that essential hypertension is not due to excess of adrenaline in the blood. An unidentified depressor substance present in the urine of normal persons has been found to be absent from the urine of hypertensive patients by Wollheim and Lange.

The hypertension about the time of the menopause, often in fat women and coincident with arthritis, has been ascribed to, as it is contemporaneous with, endocrine changes. The evidence is at the best circumstantial. Ayman and Pratt consider that the hypertension is psychical in origin; this explanation is on the same lines as Kylin's view, that hypertension is a manifestation of a general nervous disorder, especially of the automatic system. But this only shifts back the question of causation.

Pressor substances.—Many investigations have been undertaken to isolate pressor substances, other than adrenaline, in the blood, and due to disturbed metabolism or to imperfect excretion, especially of protein derivatives. Persistent, and at the same time cautious, claims have been made since 1924 by Major on behalf

of guanidine bases; in approximately 50 per cent of a large number of hypertensive subjects he has obtained evidence of an increase in the blood of a substance with reactions resembling those of guanidine; this has been confirmed by Pfiffner and Myers. Major has also observed a fall of blood pressure in hypertensive patients when induced diuresis caused an increased output of this substance in the urine. Waldbott's conclusion that some cases of unexplained hypertension may be caused by allergy was tested and contested by Cohen, Fineberg, and Rudolph. 'A distinct therapeutic success' in reducing hypertension was reported by Allen and Sherrill by restriction of the sodium chloride intake; but this was contested by Mosenthal and by Berger and Fineberg.

Psychical influences.—In 1876, at the Sheffield Meeting of the British Medical Association, Clifford Allbutt read a paper on 'Mental Anxiety as a Cause of Granular Kidney'. As acute emotion causes a temporary rise of blood pressure it has been assumed that long-continued worry, or the strain of strenuous existence, may be responsible for essential hypertension; but it must be remembered that mental strain is often accompanied by circumstances harmful to health, such as overeating and want of fresh air and of exercise. Some doubt has been thrown on this influence of mental strain by Soma Weiss's analysis of 33,000 life assurance applicants with a systolic pressure of 170 and a diastolic of 100 mm. Hg.; this showed that the average blood pressure of small farmers was as high as, or slightly higher than, that of lawyers, medical men, teachers, and members of other professions specially exposed to mental strain. Long-continued mental strain and worry are very common, and no doubt many with this history become hypertensive; but many escape and by no means all hypertensive patients have led a strenuous life. That mental worry may have some influence, especially in those with an hereditary tendency and when combined with other unfavourable circumstances, cannot be denied; but as a single efficient cause its claim must not be rated too high.

CLINICAL SIGNIFICANCE

Lastly, a few words on the clinical significance. Although symptoms may occur in patients with essential hypertension, what evidence is there that they are due solely to the persistently raised blood pressure rather than to its cause or to the effects of its long-continued action on the cardiovascular system or kidneys? It is common knowledge that hypertension may exist in persons who do not complain of any symptoms, at any rate until they learn, perhaps after an examination for life assurance, that their blood pressure is too high. The subjects of uncomplicated hypertension are prone to vasomotor instability, and hence fluctuations in the blood pressure occur more readily than in normal persons. These subjects may be free from symptoms while the raised blood pressure remains fixed at the level best suited to the individual, and so long as secondary changes, such as cardiac and renal failure, are absent. But a sudden considerable rise may precipitate discomfort just as in paroxysmal hypertension. It has been thought that the early symptoms of essential hypertension are due to functional disturbances of the blood supply of the brain, either by spasm or by causing increased intracranial pressure of the cerebro-spinal fluid.

Polycythaemia.—The red count may be increased in hypertension; in some degree it was present in 45 per cent of Kerppola's cases, and Lenaz found a definite relation between the systolic blood pressure and the red count, systolic pressures of 125, 150, and 170 being associated with 5, 6, and 6.8 million red cells per c.mm. Attempts to explain this occasional association are not very convincing. In polycythaemia rubra or erythraemia the viscosity of the blood is increased, and in Gaisböck's group of polycythaemia hypotonica the blood pressure is raised, but these cases are usually complicated by

chronic nephritis. Among 189 collected cases of polycythaemia Lucas found records of the blood pressure in sixty-six, and in twenty-one, or one-third, of these, the systolic blood pressure was below 140; this suggests that neither polycythaemia nor the constant viscosity of blood is responsible for the raised blood pressure. It has, however, been argued that polycythaemia is not due to arterial hypertension alone, but to raised pressure in the capillaries, which leads to concentration and a fall in the water content of the blood. The divergence of opinion, however, about the capillary pressure in hypertension renders further investigation and information necessary before this correlation can be considered. Izquierdo and Cannon's discussion of 'emotional' polycythaemia in relation to the sympathetic and the medullary-adrenal action of the spleen, and Lamson's earlier view that excess of adrenaline in the blood may drive the red cells out of the spleen into the circulation, might suggest that those cases of essential hypertension with polycythaemia have an excess of adrenaline in the blood. The simplest explanation of the association of polycythaemia and essential hypertension is the onset of congestive heart failure.

In conclusion, the clinical significance of essential hypertension is obviously that it is the potential antecedent of cardiovascular and renal complications.

Entamoeba histolytica Carriers and Their Treatment

By LIEUT.-COL. H. W. ACTON, C.I.E., I.M.S.

(Abstracted from the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, Vol. XXVII, July, 1933, p. 119)

INTRODUCTION

Erroneous ideas still exist as to the exact rôle played by *Entamoeba histolytica* in producing the various clinical symptoms associated with its presence in man. At first the term 'amoebic dysentery' was used synonymously with 'amoebic colitis' so that the clinical syndrome, and dysentery, i.e., the passage of frequent stools containing blood, pus and mucus, accompanied with tenesmus, was looked upon as a necessary concomitant of this infection. In ordinary civil practice this, however, is not the case as acute amoebic dysentery is a fairly rare complication of amoebic colitis—I should not place it higher than 5 per cent in an ordinary well-fed population. The incidence rises very much higher, 25 per cent or more, in the debilitated where the condition is brought about by malnutrition (famine and war) or as the result of chronic diseases such as chronic malaria, kala-azar or bacillary dysentery. The extensive ulceration of the bowel seen in some of the more severe cases of acute amoebic dysentery is due to the breaking down of the local tissue defences (kataphylaxia) as the result of a vitamin deficiency. This tissue in turn may be secondarily infected with the development of hospital phagedena, etc. The picture is seen under exceptional conditions such as war, famine, maladministration. In actual practice, however, the lesions in the bowel are usually so trivial and so slight as, at first, to interfere only with the proper movement of the gut, and give rise to constipation. I generally teach that the commonest symptom of amoebic colitis is not dysentery but constipation and that some patients have to take a daily dose of saline to prevent it.

In patients in whom it is difficult to relieve the constipation, stasis of the caecum may occur with an extension of the ulcerated surfaces. In such persons the constipation may alternate with diarrhoea due to the stasis, or there may be a morning irritative diarrhoea as the result of irritation by alcohol, foods or chill, the stools containing a good deal of mucus. This is the common type of *E. histolytica* carrier seen in practice. One must also clearly recognize that this amoeba can live a purely coprozoic life in the large bowel without producing any lesions of the mucosa or symptoms in

the patient. Dobell has shown that, in the common monkey *Macaca irus*, *E. histolytica* lives a purely coprozoic life. I have seen two such cases in man in whom numerous *E. histolytica* were found during the course of routine microscopical examinations, while at post-mortem examination two days later no visible lesions were observed in the mucosa of the large intestine. Such cases can also be recognized after careful clinical and pathological examinations. These are the true coprozoic carriers of *E. histolytica* who have no symptoms and are without ulcerative lesions in the gut. During the war I saw a unique case of this type. The patient was passing liquid watery stools containing numerous adult *E. histolytica*. There were no blood or pus cells seen and bacteriologically vibrios were not found. The patient died of broncho-pneumonia 48 hours later, and at the post-mortem examination no lesions were seen in the bowel.

The next point to determine is the factor or factors that allow *E. histolytica* to penetrate the healthy mucous membrane and gain the submucous layer. A study of the early lesions shows that over a small area of the surface epithelium of the gut there has been a breach in the surface, exposing the submucosa to the contents of the lumen of the gut. The amœba can now make its way into the tissues, and wander some considerable distance from the point of entry. Those deep down in the tissues do not contain red blood cells but often lie in little pools of lysed tissue. The adult amœba near the surface contain red blood cells and encystation occurs when the amœbæ are exposed to the contents of the gut at the surface of the ulcers. The method of entry is through some superficial trauma, and in the tropics there is ample opportunity for loss of surface epithelium as a result of injury from helminths, *Trichuris* and *Enterobius*, and from the ulcerations produced in the different types of bacillary colitis. We are not surprised to find that 15 per cent of our cases carrying *E. histolytica* have also bacilli of the dysentery group present in the stools. We have thus the mixed carrier of bacillary and amœbic infection to deal with.

The second factor that helps to keep up the carrier state is stasis. Sellard has shown that a condition of stasis of the bowel is essential before experimental infection can occur in animals. In man there is no doubt that the constipation and irregularity of the bowel that is so constantly present is responsible for the occurrence of stasis. Many of these cases find, from practical experience, that if the bowels are kept open daily with salines they are free from any symptoms. As the stasis increases the faecal contents remain in the cæcum longer and longer, so that (1) the time interval being lengthened there is opportunity for excystation of the amœbæ in the gut and increase or persistence of the carrier state; (2) the decomposition products irritate the cells of the mucous membrane of the cæcum so that an excess of mucus is poured out, hence the significance of the presence of mucus in the stools; (3) the character of the bacterial flora in the stool becomes profoundly altered. The greatest change is in the number of fine streptococcal colonies seen on the Conradi glucose plates, causing sometimes a haze on top of the medium. These are replacing the larger coliform organisms. Usually it may be stated that the more numerous the number of these colonies the more extensive is the ulceration in the gut. When there is much fermentation going on in the cæcum and large intestine the more numerous are the large moist colonies of bacteria of the ærogenes group. In the mixed type of bacillary and amœbic carrier, a varying number of opaque non-lactose-fermenting colonies may be seen which may be identified as atypical dysentery bacilli or *Bacillus pseudo-carolinus* and *B. morganii* or late lactose fermenters, as those of the metadysentery group.

The effect of stasis varies with the individual.

(1) The absorption of food may be impaired. Some of these carriers are always thin and sallow, whilst others may put on weight and remain stout.

(2) Certain hormones may be stimulated or depressed resulting commonly, in the Indian, in leucoderma and hyperadrenia, and, in the elderly European, in hypoglycæmia.

(3) Allergic phenomena from the abnormal decomposition of common food-stuffs, such as eggs, chicken, milk, flour, potatoes, may occur, and give rise to urticaria of various kinds, pityriasis rubra, toxic erythemas including erythema multiforme and asthma.

Types of *E. histolytica* carriers

Our analysis shows that there are three different and definite types of *E. histolytica* carriers, namely:—

I. Coprozoic carriers who have no lesions and no symptoms.

II. Pathogenic carriers with lesions and slight symptoms.

III. Carriers which have also bacilli of the dysentery group (mixed carriers).

The total number of these carriers amongst a given population varies. In Calcutta the percentage is between 10 and 15 per cent; in Mesopotamia, amongst the personnel who had been two years in the country, it was over 20 per cent. The figure quoted for England is between 3 and 5 per cent, as stated by Dobell. In India and the tropics the lesion in the pathogenic carrier is the commonest source of septic foci in the body. In England, as far as I can make out, practically no attention is paid to this. The reason may be due to the fact that the majority of carriers seen in the temperate zone are not pathogenic but coprozoic carriers and hence do not exhibit septic foci.

The high percentage of mixed carriers, i.e., 15 per cent amongst the Calcutta population, is important from two points of view. Firstly it shows that there is a partial correlation between the two types of dysentery organisms, and secondly it accounts for the difficulty of curing such cases by emetine only. In India there are two types of carriers who come to me for treatment; those who have failed to be cured by emetine, emetine bismuth iodide or other variations of it, and those who have symptoms not suspected to be due to the intestinal condition, such as myocarditis, hypoglycæmia, leucoderma, filarial fever.

The procedure adopted in hospital for the diagnosis of these cases is:—

(1) A specimen of the stool, preferably the last specimen passed, is sent to the laboratory daily for five days, or until a positive finding is obtained.

(2) The first stool passed in the morning is plated by a technician, immediately after being passed, on 1 per cent bile salt, McConkey's media and Conradi's litmus glucose agar. Sabouraud's medium for *Monilia* and Norris's synthetic medium for special cases are also used when the physician considers it necessary.

When there is evidence of bacterial emboli, 50 c.c. to 100 c.c. of urine is taken off and placed for 12 hours in the incubator, the urine itself being an excellent culture medium. If it becomes turbid, it is replated on McConkey's medium or Conradi's glucose agar.

Formerly, when allergic phenomena were present, we carried out the various food tests but with experience we abandoned them, as they never gave any information other than that the patient was sensitive to half a dozen, or all the foods tested. If alteration in the function of the different endocrine glands is suspected we do the ordinary standard tests: blood sugar, Gotch's test, basal metabolism.

THE *E. histolytica* CARRIERS FROM A CLINICAL AND DIAGNOSTIC POINT OF VIEW

(I) *Coprozoic carriers*.—These are fairly rare in the tropics as, sooner or later, they almost certainly pass into the next class. Such coprozoic carriers should pass normal stools without mucus; the temperature should be normal and there should be no history of symptoms of emboli, allergy or endocrine defects. Microscopically there are numerous *E. histolytica* cysts, often associated with the cysts of *Chilomastix mesnili*, *Iodamoeba*

butschlii and *Endolimax nana*. As a rule no Charcot-Leyden crystals or pyknotic cells are seen. The plating results show the flora to consist of chiefly lactose-fermenting colonies, and a very few small colonies which are usually fine yeasts and not streptococci.

(II) *Pathogenic carriers*.—These are the important cases, as from time to time they exhibit symptoms and signs of the disease in the bowel or in other parts of the body.

From a general point of view, such pathogenic carriers may appear perfectly healthy, but on questioning, a tendency towards constipation may be revealed, which has to be corrected by a morning saline; from time to time mucus may be seen in the stools. On the other hand some individuals are thin and do not lose or gain weight in spite of what they eat; the complexion may be muddy, the tongue furred, and the bowels irregular with the passage of mucus. The night sleep does not freshen up these patients who are tired out by the end of the day. These cases, unless diagnosed in time, may develop neurasthenia. More commonly there are long latent periods when symptoms are absent, unless the lesions are irritated by chills or errors of diet. In the old days the use of the flannel belt was a very good indication of the existence of the amœbic carrier state, but now, with the wholesale use of emetine in any bowel affection, the cholera belt is rapidly disappearing.

The first group of symptoms seen in these cases is due to kataphylaxia, i.e., a breaking down of the local defence mechanism in the floor of the ulcer, giving rise to emboli of cocci in the blood stream. Before these symptoms appear, the patient often complains of an increase in mucus in the stool, diarrhoea, and other intestinal symptoms.

Hæmolytic streptococci can be isolated from the stools and very often from the urine, during an attack. Sometimes, however, *Staphylococcus mollis* is found instead of streptococci. The bacterial emboli may lodge in the vessels of the nerves, causing sciatica, brachial neuritis; in the muscles, producing myositis and lumbago; in the vicinity of joints, giving rise to synovitis, arthritis and lesions in ligaments about the vertebral column. After the age of 45 these septic foci in the gut fairly frequently cause myocarditis. In filariasis they often produce bacterial inflammatory lesions round the dead or dying worms, conditions seen clinically as endemic funiculitis, filarial colic, abscess of the cord, orchitis, filarial abscess and acute filarial cellulitis. Lately Colonel R. B. Lloyd has been able to differentiate these septic cases from the cases produced by filarial toxins. In the septic cases there is leucocytosis; and the complement test against *Dirofilaria immitis* antigen is not altered or is negative. The amœbæ themselves may also leave the bowel, owing to congestion, and be caught up in the fine capillaries of the liver, causing amœbic hepatitis. I am extremely doubtful whether large adult amœbæ can ever pass through the fine filtering capillaries of the liver and invade other organs of the body. I have seen two cases of cerebral abscess secondary to extensive amœbic ulceration of the gut and from both abscesses an *Actinomyces*, probably *asteroides*, was recovered.

The second group of symptoms produced in these pathogenic carriers is due to stasis, the effects of which, on the general metabolism, should first be considered. Some carriers seem to thrive in spite of these changes, whilst others gradually become thin and pass into a neurasthenic condition. The thyroid and adrenals show evidence of loss of function—harsh skin, a feeling of cold, low blood pressure. We have seen two other endocrine defects that are correlated partially with the carrier condition. The one is leucoderma, associated with hyperadrenia in Indians; and the other, hypoglycæmia in elderly Europeans, which is the converse of diabetes, in the Indian at the same age. When there is a good deal of decomposition proceeding in the gut, the proteins of the commoner foods, chicken, eggs, milk, potato and bread, are split up probably into abnormal

end-products so that these patients now become sensitive to these common foods. This type of allergy is very commonly present in the case of urticaria of adults, eczema rubra of children, in pityriasis rubra and, more rarely, the acquired asthma of adults.

The lesions of the symptomatic or pathogenic *E. histolytica* carrier are the great source of septic foci in the gut and a cause of acquired allergy from the gut.

Bacteriological examination.—The consistency of the stool is variable in these cases. It may be constipated, with small patches of mucus, or loose with mucus and unusually offensive. Microscopically there can be detected mucus, frequently pyknotic cells and sometimes Charcot-Leyden crystals. The last named are probably some simple protein like spermin, and represent an end-product of protein decomposition: I took upon them as an evidence of stasis. I have seen the *E. histolytica* ingesting these Charcot-Leyden crystals on the floor of an amœbic ulcer, prior to encystment. The number of amœbæ in the stool is variable. They may be few or numerous, while 'minuta' forms as well as cysts may be seen. Other protozoa like *Endolimax nana* and *Iodamoeba butschlii* may be present in both cystic and vegetative forms. Bacteriological cultures on glucose Conradi plates reveal many fine streptococcal colonies, which are characteristic of the pathogenic carrier: the more acute the lesion the more numerous the streptococcal colonies. On McConkey's plates the lactose-fermenting colonies of the coliform type become fewer and fewer in number and when there is a good deal of gas-forming decomposition with stasis, numerous larger, paler and moist colonies of the *lactis aerogenes* type are seen.

(III) *Mixed carriers of amœbic and bacillary infection*.—About 15 per cent of the amœbic carriers seen at the School of Tropical Medicine in Calcutta have both infections. This point is of some practical importance as the difficulty of curing them by emetine or even emetine bismuth iodide is the cause of their being sent to us. These chronic mixed carriers differ considerably in their symptoms from the pure amœbic carriers. Reflex spasms are more common at the pylorus, upper part of cæcum, transverse and descending colon. Many of these cases have had the appendix removed and still have tenderness in this region. A few develop signs of duodenitis and even gastric or duodenal ulcer. The Gram-negative bacilli that leave these ulcers do not cause emboli. They are commonly excreted in the bile or urine and may give rise, rarely, to attacks of continued fever (e.g., *B. asiaticus*). In the urinary tract they may cause cystitis, when a cystocele is present or pyelitis, from the pressure of a pregnant uterus. Bacteriologically on the McConkey plates, in addition, one will see a few or a number of opaque non-lactose fermenters, or late lactose fermenters.

TREATMENT

The routine treatment adopted for these cases was the administration of bismuth emetine iodide as advocated by Dobell, with slight modifications. Two grains of bismuth emetine iodide powder were given at night in liquid paraffin (one drachm), as it had been found in military practice that the use of tablets was followed by their being found on the ground, unswallowed, next morning, while in the tropics they may also pass unchanged through the bowel. An hour before this dose one-sixth grain of omnopon (Roche) was given and when the patient had become drowsy the bismuth emetine iodide was administered. The course of treatment lasted 12 days but if any symptoms of emetine intolerance were observed, a day's rest was allowed between the ninth or tenth day. The full course of 24 grains was given in all cases. The stools were examined daily for six consecutive days after treatment was completed. It was not possible to carry out any more elaborate examinations to test the permanency of the cure.

The treatment was both tedious and rather drastic for the patient, but it gave the best results for the carriers with symptoms. On the other hand a small percentage, about 5 to 8 per cent, failed to be cured. After some time it was realized that most of the failures were in cases with mixed bacillary and amœbic infections. Probably it was the acidity in the gut in this type of stasis that rendered the emetine in the cæcum inefficacious.

During my researches on quinine in 1921 I found that the lethal concentration of this alkaloid was lowered from 1-100,000 at a pH of 8 to 1-10,000 at a pH of 6. Emetine I found to be almost identical with quinine at these pH's when tested on *Paramœcium caudatum*.

The next line of treatment, which was adopted only in cases of mixed infections, was to commence immunization as early as possible with vaccines prepared from the causative organisms of the bacillary infection. After the fourth dose of vaccine, i.e., on the twelfth day, the bismuth emetine iodide treatment was commenced and the vaccine treatment continued until the sixth dose. During the vaccine treatment, up to the fourth dose, calcium lactate (10 grains) and parathyroid (1/10th of a grain), morning and evening, were administered on an empty stomach and starches eliminated from the diet.

The results obtained with this treatment were very much better and failures ceased to occur. The method, however, proved too elaborate for India, owing to the bacteriological difficulties of diagnosing cases of mixed infection. It may be necessary to plate for 4 to 5 days before the causative organism is found.

Major H. C. Brown had already called attention to the value of the kurchi bark, *Holarrhena antidysenterica* (Apocynaceæ), for the treatment of amœbic dysentery. Colonel Chopra and I considered that if it were possible to make a bismuthous iodide salt of the alkaloids of kurchi bark it might be used as a substitute for bismuth emetine iodide. Dr. Sudhamoy Ghosh prepared such iodides for us. We found they were less toxic than emetine so that it was possible to give a 10-grain dose twice a day for 10 days without toxic effects. It appeared that in this way we would be able to increase the kurchi alkaloids in the cæcum to lethal concentrations. At first the results were very good and it looked as if the bismuthous kurchi iodide was to be the solution of this problem. Unfortunately at this stage the demand for kurchi bark became so great that it became valueless from adulterations, improper picking, etc. Colonel Chopra has been working on this subject and a supply of proper mature bark will have to be obtained before the alkaloid and its bismuthous salts become a reliable method of treatment.

In the meanwhile, Dr. A. C. Reed, of the School of Tropical Medicine, San Francisco, asked us to try carbasone—an arsenical compound which Ehrlich had produced during his studies with Hata on the preparation of salvarsan 606. As I was leaving Calcutta Colonel Chopra told me that he had tried it on fifty *E. histolytica* carriers with results which compared very favourably with those obtained with bismuth kurchi iodide.

Both methods are free from toxic symptoms, are efficient, and do not require retention in hospital. Further tests will indicate which is the better of the two treatments.

Reviews

THE CLINICAL STUDY AND TREATMENT OF SICK CHILDREN.—By John Thomson. Fifth Edition by Leonard Findlay. Edinburgh: Oliver and Boyd, 1933. Pp. xxxvi plus 1075, with 344 illustrations. Price, 30s.

THE first edition of this invaluable book appeared in 1893 and the fourth and last in 1925 not long before the death of its author. As Dr. Leonard Findlay says, Dr. John Thomson was a master clinician and his book reflected the experience of a life-time devoted to the study of disease as influenced by and reflected in infancy and childhood. It is therefore an excellent thing to have a new edition of his book, enlarged and brought up to date by the hand of another great specialist in pædiatrics. The character of the original book is retained. It is written largely from the clinical point of view. The best methods of examination of the different systems in young children are described, and the significance and diagnostic worth of the various symptoms and signs are given. The volume does not pretend to be a complete treatise of all diseases met with in the child, nevertheless very full descriptions are given of all the diseases commonly met with, and many of the rarer diseases are also described and many photographs of rare and unusual conditions are included. The book runs to more than 1,000 pages. The sections chiefly revised in this edition are those on nutritional diseases in infancy, rickets, acid intoxications, tuberculosis, and rheumatic infections in childhood. The section on rickets is very full and particularly interesting. It gives a résumé of all the various theories which have been held of the causation of this widespread disease, showing how each advance in medicine has produced a new and fashionable theory. It is interesting to find that Huntly, a medical missionary in India, stated in 1889 that rickets was due to absence of sunlight, and Palm who had studied conditions in India and China also concluded in 1890 that

rickets was most prevalent where sunshine was least. Their work received little notice, and it was not till 1919 that serious attention was paid to this factor. Dr. Findlay says that we are still not certain of the real cause of rickets. Fortunately however nowadays we do know how to prevent it and how to cure it in its early stages at least. The chapter on tuberculosis is also particularly interesting. Although tuberculosis is diminishing in England and Scotland, it still remains one of the commonest and most serious of the diseases of childhood. We do not perhaps all realize that 'pulmonary tuberculosis is pre-eminently a disease of infancy and early childhood. There are more deaths from pulmonary tuberculosis during the first two or three years of life than during any other age period'. An investigation of the incidence of pulmonary tuberculosis in the infants of Bengal would be of great interest. Dr. Findlay describes how sputum can easily be procured even from young children for such an investigation.

The first part of the book deals with the general clinical examination of children, their normal development and growth including a very interesting chapter devoted to the teeth, and with the feeding of infants and older children. Several chapters are devoted to feeding. Dr. Findlay holds that where breast milk is not available the best method of rearing an infant is on undiluted cow's milk, practically from birth. The iron of milk is only just sufficient for the infant's needs, and where dilution of milk is practised there is grave danger of producing anæmia. Nutritional anæmia is also very liable to occur in any child, whether breast or artificially fed, who is kept too long (more than 10 months) on a diet consisting entirely of milk.

No better book than this could be recommended for the use of those who have the medical care of children in their hands, whether specialists or general practitioners. Its clarity, balance and wisdom make it

remarkable. It is extremely well written. The print, illustrations, and general get-up are excellent.

J. M.

THE TREATMENT OF RHEUMATOID ARTHRITIS AND SCIATICA.—By A. H. Douthwaite, M.D., F.R.C.P. (Lond.). Second Edition. London: H. K. Lewis and Co., Ltd., 1933. Pp. xii plus 132, with 4 illustrations. Price, 6s.

Nor many years ago the septic-focus theory of the cause of rheumatoid arthritis held the field, to the exclusion of almost all other theories, and the term 'rheumatoid diathesis' was ridiculed as an expression only used by grandmothers and old family physicians. But the tide was now turned against septic foci, and the author of this book—as have many other distinguished physicians—has taken this opportunity to reopen the case and to examine the question of the ætiology of rheumatoid arthritis from a broader and more reasonable point of view.

The author fails to resist the temptation of delivering a *coup de grâce* to the septic-focus theory; this he does in a manner which will appeal to the average medical reader, but the figures he quotes would not, we fear, satisfy a statistician. The other chapters are of a more constructive nature.

Though we admit that it is not essential that every medical writer should be a literary stylist, we cannot help deploring the growing tendency in medical literature towards carelessness in construction and even in grammar. This book is not a particularly bad example, but nevertheless the sensitive reader will find himself shocked repeatedly. Throughout the book, *cases* recover, consult the author, and even suffer *prodromata*. 'Actually the number of recoveries was three times as great as that which improved after removal of local infection', and 'the terms "chronic arthritis" and "rheumatoid arthritis" appear to be regarded as synonymous by some authors, thus adding further to the existing confusion', are examples that occur in the first few pages; after this the reviewer acquired a certain degree of 'immunity' against further shocks.

However, physicians will find in the book a clear exposition of the most modern, and in our opinion the most reasonable, views regarding the ætiology of both rheumatoid arthritis and sciatica, and a valuable guide to the treatment of these and allied conditions.

CUTANEOUS NEOPLASMS.—By Norman Paul, M.B., Ch.M. London: H. K. Lewis and Co., Ltd., 1933. Pp. xii plus 154, with 62 illustrations. Price, 10s. 6d.

CONTINUOUS bright sunlight day after day is now being found not an unmixed blessing and in Australia, where such conditions exist, evidence is rapidly accumulating that excessive insolation of the skin is a predisposing factor to the development of malignant disease.

The opportunity presented by the unusually large number of persons who develop malignant disease in Australia has been made use of by the author of this book, and he has produced a valuable volume on neoplasms of the skin. Although consideration of malignant conditions occupy the greater part of this volume benign neoplasms also receive their due amount of attention. The book is copiously illustrated by excellent photographs and on the whole is clearly written, but we are sorry to see that the author talks of 'tubercular' skin lesions, when referring to disease caused by the *Bacillus tuberculosis*, such a careless use of this word is especially reprehensible in a dermatologist.

To say that the book is printed and published by Messrs. H. K. Lewis and Company in their usual style will be sufficient commendation to those readers who are familiar with this well-known firm of medical publishers. The book may be summed up as an eminently useful and pleasing production.

P. A. M.

BLOOD DISEASES IN CLINICAL PRACTICE.—By Prof. Dr. P. Morawitz. Translated from the 2nd German Edition by A. Piney, M.D., M.R.C.P. London: J. & A. Churchill, 1933. Pp. viii plus 102. Price, 7s. 6d.

THIS small book is a translation from the German by Dr. A. Piney, himself a contributor of several valuable shorter books on hæmatology. This book only deals with the purely clinical aspect of blood diseases and is little more than a record of the wide personal experience of the author. It is a useful résumé of the subject giving the salient points of the diseases of the blood and blood-forming organs and as such might be read with profit by a busy practitioner as a refresher, but it cannot usurp the place of the larger books. In the reviewer's experience it is unique among modern books on the blood in that it has not a single drawing or coloured plate.

ORAL SPIROCHÆTES AND RELATED ORGANISMS IN FUSO-SPIROCHÆTAL DISEASE.—By David T. Smith, M.D. London: Baillière, Tindall and Cox, 1932. Pp. xii plus 243, with 53 figures. Price, 26s.

THIS is a very useful book dealing with one of the most important groups of anaerobic organisms, the fusiform bacilli, the spirochætes and the spirilla of the mouth and the intestines, organisms which generally do not receive adequate treatment in medical bacteriology. These organisms produce a wide variety of acute and chronic lesions in various parts of the human body. In the first five chapters the biological and cultural characteristics of these organisms are described and the rest of the book is devoted to the description, diagnosis and treatment of the various fusio-spirochætal infections. A very useful bibliography containing 822 references bearing on the subject is appended. This is a book that will be valuable to all bacteriologists as well as to the clinician.

C. L. P.

THE ADRENAL CORTEX—A SURGICAL AND PATHOLOGICAL STUDY.—By L. R. Broster, and H. W. C. Vines. London: H. K. Lewis and Co., Ltd., 1933. Pp. 94, with 4 coloured illustrations. Price, 6s.

THE publication of this little book has at last removed a long-felt want amongst English-reading medical men. The subject of the adrenogenital syndrome attracted the attention of scientific men only comparatively lately and their observations have so far been published as individual contributions, in different medical journals, both in England and abroad. We congratulate Mr. Broster and Dr. Vines for taking the initiative and placing all the facts together in this volume, for the information of the general medical profession. After a very careful and painstaking research, they have discovered a new method of study, by special histological means, of the cytology of the adrenal cortex. There was no reliable method for demonstrating the pathological condition of the suprarenal gland under the microscope and the Ponceau-fuchsin technique for the histological exhibition of cell granules of a definite character will be hailed by everybody interested in the subject. For this reason, the writers deserve our warmest thanks.

The book is divided into three parts. In the first part, the usual clinical picture of the adrenogenital syndrome with virilism and its different varieties have been described. The results of the complete investigation, including unilateral adrenalectomy, of ten typical cases have also been described. In all of them, the cortical cells gave a very strong fuchsinophil reaction when stained by the authors' technique, indicating an abnormal functional activity of the cells, which appears to be responsible for this tendency to sex reversion. In the second part, a further series of ten cases of various degrees of virilism, but without any gross enlargement of the adrenal glands, are described.

These cases show lack of development of the genital organs with cystic degeneration of the ovaries. This series includes interesting descriptions of two hermaphrodites who were brought up as females but were really undeveloped males. In the third part, the authors describe the actual technique of their special stain and also discuss the subject, on an histological basis, from several points of view. They have also given a philosophical discourse on the probable causes of sexual reversions and masculinization of females. The four coloured plates, illustrating the reaction to their special Ponceau-fuchsin staining, are excellent.

While going through the book, certain mistakes have been found. The following may be cited: Page 26, under sugar tolerance curve, .96 should be .096; page 32, under blood count, C.I.9 should be .9; under blood cholesterol, .15 mgm. should be either .15 per cent or 150 mgm.; under sugar tolerance, 15.5 should be .155 and 15 should be .15; page 50, under blood sugar curve, .9 should be .09; page 52, under haemoglobin, .96 should be 96 per cent.

Sugar tolerance (Avery) does not express anything. Apart from these inaccuracies, the book contains excellent material for study and we fully recommend it to students, practitioners and research workers alike.

Annual Reports

ABSTRACT OF A REPORT ON INVESTIGATIONS INTO THE PROBLEM OF OEDEMA IN SIERRA LEONE. BY W. A. BURNETT, B.Sc., M.B., Ch.B., D.T.M. & H.

A PATHOLOGICAL condition diagnosed as the oedematous type of beriberi has been present for many years in Sierra Leone; at intervals outbreaks of epidemic severity with a high rate of mortality occur.

The problem of beriberi is one which has been noted in Freetown Prison for at least the last forty-eight years. At this institution it had been reported under several diagnoses, to wit, oedema, dropsy, beriberi, dysentery with dropsy. Various spasmodic references have been put on record until recently when an investigation was made by Professor Blacklock in 1922, and later in 1929, when Drs. Leitch and Watson undertook an intensive and exhaustive survey of the condition at the Freetown Prison. The outcome of their work was that drastic alterations in management were suggested, together with the allowance of a diet very rich in vitamin B and of high calorie value, as much as thirty-five hundred calories being allowed to adult male prisoners on sedentary occupation. 'There is no excuse for its existence, as it can be guarded against by easily arranged and inexpensive measures; given an adequate diet, all that remains is to see that the vitamin B content of the diet remains up to standard', quote the joint authors of 'Beriberi in the Freetown Prison'; yet despite the most strict adherence by the superintendent of prisons to this dietary advice, coupled with the daily inspection of the inmates' food rations by the prison doctor, the medical officer in charge of Freetown Prison continued to find this 'oedema' cropping up among the prisoners and culminating in a severe outbreak in 1931. A diet rich in yeast, cod-liver oil, fresh vegetables and fruits, despite the reputedly high content of vitamin B, had failed to prevent a serious recurrence of the condition. At that time large quantities of marmite and bemax were being given without the success one would have expected from these 'vitamin' foods, if the condition had been one purely of avitaminosis. It was only after an alteration of the diet to consist of new rice, a step suggested by Mr. Biddle, the superintendent of prisons, from his lifelong experience of the condition, that a mass improvement set in and no new cases were reported. It seems a great pity that his valuable first-hand knowledge of this disease does not appear to have been utilized to better advantage in some of the previous epidemics.

During the period from August 1931 to January 1932, there was a very considerable outbreak of the oedematous condition here, involving Freetown Prison, Wilberforce Barracks and Kissy Asylum. A number of Freetown inhabitants, too, complained of the disease and were treated at the Connaught Hospital.

The condition clinically.—The syndrome takes the form of a varying degree of non-albuminuric oedema, usually well defined in the limbs; of dyspnoea on the minimum exertion and of tachycardia with enlargement mainly of the right heart; of muscular weakness with deep muscular hyperaesthesia; of gastro-intestinal disturbances, generally constipation, sometimes followed, in the fatal cases, by diarrhoea and faecal blood, and of such nerve changes as are displayed by diminution of, or loss of, tendon reflexes, localized and often transient anaesthesia and deep hyperaesthesia. Difficulty of vision is present at times. There may be, and generally is, a slight pyrexia, but the fever does not usually exceed a range of 99°F. to 101.5°F.

The blood examination does not reveal any obvious pathological change. There is a slight hydremia associated with diminished red cell count (average 4,300,000 per c.mm.) and with a lowering of the haemoglobin content to 70 per cent. The colour index is generally found to be in the region of 0.81. Although the white cell count ranges from a value of 7,000 to 11,000 per c.mm., the most marked change in this aspect is the decided shift to the left in the Arnetz index. Quite a considerable proportion of bilobed and trilobed polymorphonuclear leucocytes is to be seen.

Records of the blood pressure are found to vary in the people affected in accordance with the state of the bowel and of the heart. During the phase of subacute or chronic constipation, there is a definite elevation to 150-170 mm. Hg. systolic (90-106 mm. Hg. diastolic) but when recovery sets in or the intestinal stasis is relieved for a few days this blood pressure steadily falls by 20-30 mm. and is maintained at a lower level, 130-140 mm. systolic (70-84 mm. diastolic). Where the signs of pericarditis with effusion are present coupled with diarrhoea, the blood pressure is constantly low (100 mm. systolic, 60 mm. diastolic); when these patients are recovering, which they do very slowly, the blood pressure is equally tardy in rising to the normal and, in the cases under review, no one exceeded a final reading of 118 mm. systolic, 72 mm. diastolic.

The urine shows none of the ordinary abnormalities. It is free from sugar, diacetic acid, acetone bodies and albumin, but although just slightly diminished in

amount it contains an excessive quantity of phosphates, which separate on cooling.

WILBERFORCE BARRACKS

The conditions at Wilberforce Barracks, where are stationed soldiers of the Royal West African Frontier Force, render the study of epidemic and general diseases much simpler than among the general African populace.

The barracks.—The barracks' compound is situated on a hill sloping fairly gently downwards in all directions. The lines of huts are placed in parallel rows running north and south. The huts occupied by the soldiers are of mud construction, measuring over all 45 feet by 34 feet. They are separated from one another by a minimum clear space all round varying from 18 feet to 33 feet wide. On each long side is a verandah 6 feet wide. The huts are subdivided by mud walls 8 feet 6 inches high and 6 inches thick, into eight rooms each measuring 10 feet square. The walls do not extend to the roof, which, at the highest point, is 11 feet. A ceiling is formed by stretching over the top of the walls a horizontal layer of wide-mesh wire netting. The floors, including the verandahs, are built up 3 feet 6 inches above the ground level. Each room has one window, capable of being opened, and one door, but in some of the huts the partition wall has been cut to make an internal communication between adjacent rooms. During the day the rooms are cool, chiefly on account of the covering of thick thatch on the corrugated iron roof, which is carried well down over the verandah to provide shade and to reduce the ingress of reflected heat from the ground. All the rooms are more or less infested with bedbugs (*Cimex lectularius*, *Leptocimex boueti* and *Cimex rotundatus*) and the possibility of migration, not only from room to room, but from hut to hut, is far from remote.

Cooking.—Generally, the cooking is conducted in communal kitchens, which are huts with freely opened partition walls. Individual fires are employed and the cooking is conducted by the women, who use the kitchens as convenient places wherein to beat the rice by the native mortar and pestle method.

Latrines.—The latrines are well isolated and at least fifty yards from the huts of the compound. Men and women use separate buildings, which are erected to accommodate the dry bucket system. The faecal matter is buried in a large pit, 200 yards from the nearest hut and to the prevailing leeward side of the compound. These conveniences are kept clean and tidy and are inspected regularly by the sanitary inspector allocated to the barracks.

Drainage.—Open surface gutters are in use for drainage with water channels running away from each hut. As the compound is built on rock on an exposed sloping hill the drainage is ample, well designed and sufficient.

Water supply.—The water supply is brought in by pipe line from the hill station supply and laid to convenient automatic stop cocks; no waste is permitted.

Rubbish bins.—Small rubbish bins with steel lids are located near the water taps (about 20 feet from each one). These appear to be used with disciplinary care, as no evidence is visible of indiscriminate scattering of rubbish and there are sufficient bins to accommodate the refuse without piling it up around the receptacles. They are emptied daily and the rubbish is incinerated.

Wash-houses.—Wash-houses are separated from the compound on the eastern side of the hill.

On the whole the compound is tidy, well kept and efficiently managed, as far as sanitation is concerned.

The epidemic

At the end of October 1931 the disease was first brought to notice by a soldier complaining of swollen legs, constipation and breathlessness on exertion. His heart sounds were soft and muffled but there were no valvular murmurs. The urine displayed no abnormalities

(albumin, sugar, acetone bodies) but it contained an excessive amount of 'earthy' phosphatic deposit. It was considered advisable to have the man admitted to and treated at the Connaught Hospital where, however, he died two days after admission. He had been ill for seven days.

The necropsy revealed acute pericarditis with effusion (8 oz.), cardiac enlargement, pulmonary oedema, scanty volume of fluid in the peritoneum, hepatic oedema, enlarged gallbladder with normal bile, and oedema of both legs extending only to the knees. The cause of death was diagnosed as beriberi of the wet type and pericarditis with effusion.

Survey of troops.—On account of the presence of beriberi at Freetown Prison and of the information that the troops were being issued with rice from the same contractor who supplied the prison, it was deemed essential to take urgent measures to round up all affected soldiers. Consequently, a survey of the entire personnel at the soldiers' compound was undertaken to isolate similar patients and to anticipate early cases.

All the huts and rooms were numbered and a plan was made of the compound, showing such details as position of huts, kitchens, latrines, drains, rubbish heaps and water supplies. Small metallic discs were figured with the hut and room numbers. They were issued to the responsible occupants of each room, with the instructions that on any complaint of sickness by any inmate, such patient should appear with the disc at the morning sick parade, so that any disease, whether of an infectious nature or otherwise, could, by comparison with the numbered plan at the medical officer's hut, be localized immediately and, if need be, suitable steps taken at once. The misuse of discs by persons is an offence punishable on the owner of the disc, and loss of disc is notifiable immediately.

A census of the soldiers' lines in the compound was made.

The oedema cases.—The serious cases of oedema were admitted, some to the Connaught Hospital but others chiefly to the hospital at the barracks, where they were treated along several lines to find, if possible, an efficient remedy. In the barracks' cases the diet was kept unaltered and consisted of rice seasoned with red pepper, palm oil and, occasionally, with the addition of a small piece of beef or fish.

The other patients and early cases were grouped as ambulatory subjects in experimental classes and various prescriptions were given each group, with the possible object of obtaining better statistical data concerning treatment.

All these subjects were given medical treatment daily for an observation period of eighteen days and the results were noted. They remained on the same diet to which they had been accustomed and no new rice was allowed, nor was there any special issue of foods rich in vitamin B. If improvement did not follow within eighteen days the subjects were switched over to a line of treatment which had been proved to be successful for other groups. Thus, in some classes, no betterment was observed, in fact, many patients became worse but when given the 'calcium lactate purge' mixture or calcium lactate and sodium citrate, they all cleared up rapidly in ten to twelve days. No fatal issue attended the experiments although many ambulatory subjects had well-defined oedema.

Hospital cases.—Generally, the patients treated in the hospital cleared up more rapidly due to the rest in bed and to the better conditions of warmth and shelter maintaining in the building.

The food of these patients was what they had been having in their huts at the barracks' compound, where it was prepared and then brought over to them. They each consumed daily about 1½ lb. rice, cooked with the addition of red pepper as curry, palm oil (about 2 ounces) and some dry fish.

Very few of these patients received beef every day but they all had it twice a week. On other days the

protein was obtained in the form of dried fish. In general, as far as protein-rich food-stuffs is concerned, the average soldier lived on what may be colloquially termed the 'hunger and burst' principle. The meat ration is reduced to a minimum till the week-end and, especially, till pay day at the end of the month, when, at Wilberforce Barracks, extra cattle are killed to supply the market demand. It was fortunate that the majority of the hospital cases did not receive the surfeit of beef during their stay in the hospital. As will be shown later, excessive amounts of meat have a peculiar influence on the course of the disease, in that the oedema tends to be reduced with a diet rich in animal protein. This aspect of the condition was confirmed by observations on the inmates of Freetown Prison.

Treatment survey.—Surveying the treatments, it was considered that, to be successful, it was necessary to include calcium lactate, preferably made easily assimilable by exhibiting also the alkaline effect of sodium citrate and to add an efficient saline purge. Although, however, this calcium lactate and purge treatment made the oedema vanish and enabled the patient to feel well and to be able to resume duty, it cannot be considered a cure provided the subject continues to eat faulty rice. So long as this type of treatment is taken, the rice could be consumed without any considerable increase of the oedema following, entirely, I think, because of the purging effect of the saline and of the vasotonic influence of the calcium salts. When the treatment was withheld the dropsy returned in about eleven days and it was always preceded by a bout of constipation. On the other hand the treatment effected a permanent cure of the condition after six months, when the men ate new season's rice, even despite the onset of attacks of constipation or when the 'oedema-producing' rice was cooked as I directed.

Distribution of cases.—Concerning the distribution of oedema among the entire colony at the compound, the table below demonstrates the age and sex incidence:

Total cases	.. 54	Men	.. 30 : 226	13.3%
" population	554	Women	.. 19 : 185	10.3%
" incidence	9.7%	Servants	.. 4 : 63	6.3%
		Children, boys	1 : 31	3.2%
		Children, girls	0 : 49	0.0%

Among the entire inhabitants, the incidence of oedema was 9.7 per cent with a sex and age distribution as shown above.

That the soldiers are exposed to the strain of physical training, to drill in comparatively heavy equipment and to strict discipline are potential causes of the high relative incidence of the condition among their numbers. Women do not lag far behind in that they have fairly hard work to do washing clothes and preparing rice by pounding in the native mortar with heavy wooden pestles. The boys (servants) come under a special category. Some are attached to the native soldiers and others to the European officers. Among the latter no oedema was observed; whether or not this is due to the lavish treatment by their employers or to the enhanced opportunity of participating at a better commissariat is unknown, suffice it to remark that none of these boys showed any signs of chronic starvation and they did not eat the same rice as was consumed by the soldiers.

The female children, by a close association with their mothers, are better looked after than the male children. This may be the cause of their increased resistance to the condition.

Multiple infection.—Infection ought to be considered in terms of multiple infection, where two or more people in the same room exhibit the sickness at the same time. Forty cases were found in rooms occupied by more than one individual, yet, although the total number of occupants of these rooms amounted to ninety-eight, only seven cases of 'dual' infection occurred.

Of the forty, thirty-three were married people but of these only five couples were found to be suffering at the same time. In one case a man and his child were affected and in another two of three sisters, so that, in

all, seven instances of 'dual' infection were displayed, that is, the disease affected only fourteen people, who were daily in the closest contact with their neighbours. During any part of the work there was no indication of one individual being affected and a neighbour later after a definite incubation period. This idea of infection by contact and by vectors had carefully to be considered because of the peculiar suspicion of an infective agent in the prison cases. It will be brought up again later.

The theory of an insect vector merits further attention, when the loci of the disease are considered along with the plan of the compound. The bulk of the cases was confined to huts, which are all situated together. The possibility of an insect vector disease became apparent, but, as the work progressed, it was partly relinquished in view of the theory of rice poisoning expounded later. After all, even allowing the chance of a disease being carried, these people were all, more or less, eating the same food which, if proved to be toxic, would eliminate the necessity of considering an insect-borne disease. It is considered superfluous to promulgate theories of infection and of insect vectors, if in a mass attack all the members of a community partake of the same type of food, which is shown to be detrimental to health.

Rice at Wilberforce Barracks.—At the time of the outbreak, I examined, in conjunction with the superintendent of prisons, specimens of rice supplied to the Royal West African Frontier Force. The samples had a musty smell. I found the rice to contain a high percentage of old dead and fungoid-diseased grain (29 per cent) and to be mixed with a small percentage of bored and broken grains. Weevils, rice bugs and maggots were present. A large percentage of the rice showed black and dark brown discoloration, extending from the pericarp inwards to the starch.

The soldiers complained that when they ate this rice they suffered from colic and abdominal trouble, some with constipation, others with diarrhoea. In all cases of oedema at Wilberforce Barracks, there was a history of gastro-intestinal stasis occasionally with colic.

Effect of washing rice.—To make it a safer food, I recommend that the rice be cleaned in water and cooked in a special manner. This consists of washing thoroughly in cold water, placing the rice in a pot with water to cover, just bringing to boiling point and throwing away the yellow-brown boilings. Fresh clean water is then added and cooking is continued till the rice is soft and edible. By these means it is maintained that soluble toxins are dissolved and thrown away but any vitamin B is retained undestroyed. A number of women in the compound had been using this method before I recommended it and in no case was any of their family circle affected. On the other hand, in every case of oedema, although quite a number washed the rice in cold water before cooking, all invariably conducted the cooking of the rice by adding just sufficient water and boiling till the grain had softened and absorbed all the water. There was no mention of throwing away the initial boiling water. Recovery from the oedema became permanent when this method was adopted.

One case is of special interest in this consideration. A patient (a) had been admitted to the barracks' hospital and treated with calcium lactate and sodium citrate. In the hospital he shared the rice of another patient (b), a case of bronchitis, whose wife threw away the first boilings. Both men recovered and returned to duty but a fortnight later (a) was readmitted to the hospital where he informed the dresser that he had gone back to his own wife's method of cooking, in which all the water was boiled into the rice. (a) recovered and did not show any relapse to the oedematous condition, when he consumed the rice after the initial boiling water had been rejected.

Previous outbreaks.—On account of the difficulty of obtaining accurate data, any reference to previous outbreaks of oedema at Wilberforce Barracks is scanty.

The daily record of medical complaints was gone over for the last three years in the hope of glean some such information.

Although there is a fairly constant relation between constipation and œdema (constipation always preceding œdema), the same does not necessarily apply to rheumatism. This may be merely a question of nomenclature. The terms myalgia, rheumatism, lumbago, sciatica, fibrositis, muscular and joint pains have all been employed and it is difficult to know if previous medical officers considered rheumatism in the narrow sense of 'joint pain' or if they imply the aspect mooted by Professor R. Stockman of Glasgow University of a disease essentially of overgrowth and inflammation of the fibrous tissue, no matter where disposed this essential packing tissue may be.

In general, Drs. Leitch and Watson's work confirms these observations on the correlation between rheumatism, œdema and constipation, although they do not indicate that gastro-intestinal disturbance may be a forerunner of beriberi œdema.

I am told, too, that the late Dr. Young commented on the correlation between gastro-intestinal disturbance and dropsy, when he was medical officer at Freetown Prison.

Mr. Biddle's experience, also, is most helpful. He states that he does not remember having seen a case of beriberi that was not preceded by a history of gastro-intestinal upset, taking the form of constipation and later of diarrhoea.

The last epidemic had been present at the Freetown Prison and at Kissy about August 1931, but it did not break out to any extent among the Royal West African Frontier Force until early October 1931, when it rose rapidly to a peak value in November and steadily declined. It has since disappeared (January 1932). From information received from Mr. Biddle, there definitely was an issue of diseased rice to the Royal West African Frontier Force in July 1931. Any inferred incubation period cannot, however, be set because the troops drew this rice from the quartermaster's store as required, therefore, of necessity, the stocks held by the soldiers were of variable amounts. Good rice has since been issued to the troops and no new cases of œdema have occurred.

Outcome of the work.—The inhabitants of the Wilberforce Barracks' compound continue their simple diet of rice, palm oil, pepper, curry, with an occasional portion of fish or beef and a small amount of fresh fruit. No added vitamin products like beimax, marmite, yeast and cod-liver oil are taken with the food. They live an open air life on an exposed part of the country. Essentially, their conditions are the same as they were during the outbreak of œdema, yet merely since changing the rice and/or method of cooking, œdema has been reduced here to the vanishing point by employing these simple means, and by ensuring that, through the quartermaster's department, a supply of good sound rice is issued to the troops.

All the patients who contracted the disease during the last epidemic have since been examined at intervals and found to be well. There is no evidence of permanent injury in the way of œdema, cardiac disability or nerve changes. In my opinion, this cannot be claimed simply as a victory for treatment by calcium salts and by purging alone but I consider that it is of foremost importance to ensure that these people are supplied with rice in good condition and not showing signs of deterioration.

KISSY ASYLUM

During the enquiry, this institution was under the charge of Dr. Easmon, who kindly assisted me, as far as possible, with statistical data concerning the condition at the asylum. There was no history of any previous outbreaks but during the present epidemic no less than twenty deaths occurred from August to December 1931.

Although I was responsible only for the post-mortem examinations and I performed the majority of the

necropsies, I made a few observations on the housing conditions and on the diet of the inmates.

Accommodation.—The majority of the patients were accommodated in large wards, with beds the regulation distance apart and without overcrowding. The clothing and bedding were clean and did not show signs of verminous infection. The walls of the wards were made of a mud-cement composition, parts of which had been broken in places. No bedbugs were found. There did not appear to be evidence of any patient having the infection carried from his immediate neighbour, as will be presented in cases which occurred at Freetown Prison. In general, the inmates were clean and showed signs of kindly treatment and good care.

Dietary.—At the same time I visited the kitchen of the asylum and inspected the rice bin, where there was stored a quantity of rice containing old fungoid grains, bored and broken grains and discoloured grains. Weevils and maggots were seen in the bin. This rice contained on examination 33 per cent of pericarp as shown by the Vedder and Feliciano method. The rice was supplied from the Freetown Prison and came from the same source as was used in Freetown Prison and Wilberforce Barracks.

The inmates of the asylum had their rice cooked in a large open boiler, into which the grain was placed, water added and boiled for twenty-five minutes. Any surplus rice water was not discarded but was added to soup, although the cook informed me that generally the water more or less all boiled into the rice. During the epidemic there was no doubt that Dr. Easmon relying on the diagnosis of beriberi due to avitaminosis did all in his power to cope with the condition by allowing a most liberal diet, high in calorie value and excessively rich in added vitamin products. This had not the slightest effect on the course of the epidemic.

Observations.—In the course of my duties, I interviewed several inmates. In November I found eight cases of œdema most of whom came ultimately to necropsy before the year ended.

On enquiry, I learned the treatment consisted of a very liberal diet of rice, greens and meat, with marmite as an additional source of vitamin B. To the patients suffering from pericarditis a cardiac mixture called 'mist. beriberi' was exhibited.

Unfortunately, in all the cases I saw, it did not have the desired effect, even when coupled with large doses of vitamin B (supplied in the form of marmite). However, as my duties did not extend to treatment of the cases, the observations I made at Kissy Asylum, where the outbreak was very serious, were confined to post-mortem examinations.

HOSPITAL CASES

Out-patient department.—In November 1931 many cases of œdema cropped up at the out-patient department. They displayed the same signs as were present among the troops and among the prisoners at Freetown Prison. Œdema of feet and legs was commonly coupled with a history of chronic constipation. The urine showed no abnormalities but had an excessive amount of 'earthy' phosphates which, in these cases, may have been due to reduced water intake with the concomitant result of higher concentration of urinary salts. Many had præcordial distress and breathlessness. In one man, a pauper, who had been consuming black mouldy rice, œdema of the abdominal wall and of the skin over the sternum was found in addition to dropsy of the lower limbs.

All the cases were requested to furnish samples of the morning urine and of the rice which they generally had been using. Thirty-six cases in all were observed.

One young girl (aged twelve years) brought a new sound rice, which turned out to be recently purchased, as she did not like to show the old rice which she had been eating. Two patients, sisters, had been for several months eating parboiled rice, in which the grain was large and white with no pericarp remaining. They were treated as cases of true beriberi avitaminosis.

They were given cod-liver oil, fresh tomatoes and other fruits and advised bema, upon which the condition slowly abated. They became perfectly well after eight weeks treatment, but it was learned they had commenced to eat, during the course of their treatment, new season's rice, of which they brought a sample. It was not parboiled and contained 58 per cent pericarp.

A fourth subject was admitted to the hospital as a case of dry beriberi. He had been serving on board a ship on which he stated old rice had been issued. He improved on a full diet of bread, butter, meat, fish, eggs, milk, potatoes, fresh fruit without additional accessory food substances and he was discharged with complete recovery four weeks later.

In the remaining thirty-two cases treated, all the rice samples examined were of poor grade, containing discoloured grains, fungoid grains and signs of weevil activity. These subjects were all treated by the calcium lactate and purgative method and all cleared up within twenty days of treatment; at least after sixteen days they showed considerable improvement, had their mixture repeated and did not report again, except for four cases whose improvement was sluggish but positive and who disappeared after twenty-eight days under casual observation.

All these subjects in the out-patient department were advised about rice and cooking and most of them stated they used up their rice stock by altering the cooking.

In-patients.—Twelve cases were admitted for observation. Urinary examination in all cases but one revealed no albuminuria or other of the customary abnormalities but at first all had excessive phosphates. The one exception was a case of subacute nephritis with albuminuria and casts. In the remaining eleven, there was a constant history of chronic constipation, rheumatic pains, slight palpitation and breathlessness on exertion, tender calf muscles and oedema of the legs to the middle of the thighs. Ten had partial anaesthesia (loss of heat, tactile and pain but not of cold) over the pretibial area. The remaining one had diminished sensation only to touch and temperature, pain being present. The tendon reflexes were variable. On admission, they all had slightly elevated blood pressure (average systolic 152-164 mm., diastolic 90-106 mm.) and with the rest in bed and treatment this was steadily reduced (systolic 123-142 mm., diastolic 80-81 mm.). Two cases complained of difficulty with vision and of photophobia. One had increased intra-ocular tension and signs of early glaucoma, which, however, cleared up on treatment.

The diet was standard for all these patients, termed 'full hospital diet', which was composed of rice, greens, beef, tea, sugar and dry bread. The medical treatment was grouped as at the Wilberforce Barracks Hospital:

Results.—These eleven patients reported in one month after discharge and all remained normal, except one, who had been unable to purchase good rice or to have his food properly cooked.

Reverting to the Connaught Hospital groups (a), (b) and (c), it was shown that in:

(a) Calcium lactate and iron tonic there is a tendency to constipation which is considered to be responsible for the delayed recovery.

(b) Calcium lactate and purgative act almost as rapidly as simple enemata but at Connaught Hospital the recovery period is faster than at Wilberforce Barracks where the diet is of poorer quality and less liberal.

(c) The enemata results are of interest. These subjects were allowed (group C-1) the same diet as the others in groups (a) and (b) but they had twice daily a simple water enema without soap, using a quart of water each time. Copious foul-smelling results were obtained at first with hard inspissated faeces. After four treatments the washings were returning clear, except with traces of mucus. The odour had almost gone and the patients were looking obviously improved. The expression was brighter, the eyes less sallow and, most annoying of all it was with difficulty that they

were persuaded to remain in the hospital, possibly an aftermath of the strenuous treatment. In group C-2 enemata and diet, with rice replaced by bread and potato, the speed of recovery was the same.

FREETOWN PRISON

Oedema has been present in the Freetown Prison for at least the past forty-eight years and notifications have repeatedly been made to vague outbreaks of a condition of dropsy with dysentery. It has been only within the past few years that the disease has been labelled 'beriberi', especially when the final stages of the condition have been observed. Recently the work received intensive study in the hands of Professor Blacklock and Drs. Leitch and Watson.

Previous work.—Mr. Biddle's observations are those of the layman, unbiased in outlook and unsteeped in the lore of medical diagnosis. As such, I think they have to be considered with respect, especially also, as he has had constant contact with the disease for at least eighteen years. He has remarked that all the epidemics occurring at the prison since 1914 have invariably been preceded by gastro-intestinal symptoms, chiefly of a dysenteric nature.

The particular causal agent, whether bacterial or otherwise, has never been determined with any measure of success, and Drs. Leitch and Watson were unable to track down any organism to which might be attributed the disease. They refer to one case, in which they found only the common organisms (*B. coli communis*, *B. megatherium*, *B. friedlanderi* and *B. morgani*) to which none of the pathological findings were attributed. They came to the conclusion that this disease was definitely due to 'B' avitaminosis.

The superintendent of prisons makes a valuable observation, in that, if within a few days after the beriberi had been diagnosed, the patient developed a mild attack of diarrhea, he usually died, whereas all the cases who suffered from a prolonged and severe attack of dysentery recovered from the beriberi condition. These curious phenomena had also been commented upon by Dr. Butler in 1914 and the late Dr. W. A. Young in 1919. Young went the length of isolating every person on admission until he was proved free from infectious disease. In view of the purging effect of the treatment I adopted at Wilberforce Barracks and at Connaught Hospital, this observation is of great interest in that a similar absence of intestinal stasis is the net result both of treatment by purgatives and of chronic dysentery.

Theory of infection.—Commenting on the possibility of an infectious disease, the superintendent of prisons states that during the last epidemic (1929) the first patient was an assistant warder, Lamina, who was in charge of the carpenters' workshop. He died after about ten days' sickness. The next case, also fatal, was a prisoner, Sandi, who worked under Lamina's supervision. When the epidemic was almost at a peak, another warder, Yamba, took ill after he had been allocated duty at 'D' block, where the majority of the cases were under observation. In this subject a long history of dysentery of two months' duration was noted and, although he made a remarkable recovery, he was no longer fit for the service.

Continuing his observation, Mr. Biddle makes note of a prisoner, Abu Lemberg, who had been recommended for the radical operation for double hernia. On account of his poor state of nutrition, he was admitted to the hospital and allowed a liberal diet. His physical state became so much improved as to enable him to be fit for the operation but, just at that time, two epidemic cases were admitted to the hospital and confined to beds on either side of his. A few days later, in spite of his most liberal diet, including tomatoes and other fruit, Abu Lemberg developed the disease from which he managed to recover.

Mr. Biddle makes reference to the large number of cleaners who suffered during this (1929) epidemic. Although normally eighteen are allocated to the task

of removing, emptying and cleaning the commodes of the entire prison, the incidence of cases in this section was very high, as instanced by the fifty-six who suffered in a population of 218 men. It was considered that there was a grave risk attached to this work and even the men themselves had the impression that it was of a deadly nature. The superintendent of prisons tells me of one man, who belonged to a particular group under survey, and to whom this task was allocated. The prisoner did not remonstrate but merely remarked to Mr. Biddle that if instructed to do so he would perform the job but 'he go die'. A short time later the man fell ill with the epidemic sickness and succumbed. However, this may have been but an example of the native's fatalism.

On their face value these incidents would appear to support a theory of infection but sight must not be lost of the point that all the men were participating in the rice common to everyone's diet and that the cleaners, who suffered most, also had the hardest physical work to perform, which might possibly be sufficient to overstep the low threshold that the average African native shows towards disease. Hard physical exercise had been recommended in the treatment, an outcome of the theory (Leitch) that oedema attacked chiefly the sedentary workers. Many untoward and fatal consequences have resulted following this advice.

Coupled with the case of Abu Lemberg are the following two incidents to display that, despite the diet rich in vitamins and of high calorie value, the spread of the disease was not retarded by taking care of calories and vitamins alone. Prisoner V. Caulker had had, over a long period, an extra ration of one pound of bread and one pint of milk in addition to his ordinary full diet, yet he was badly affected. Prisoner Sherka was granted extra bread (one pound daily) on account of his old age but he, too, developed the disease.

When I took over the Research in November 1931, my work did not permit of treatment or of intensive experimental observations on the patients, who were under the control of the medical officer in charge of the prison and the time had to be devoted to such aspects as were included in the biochemical and biological research. In the early stages, any work consisted of collecting samples of rice, pericarp and dust and of observing the food of the prisoners.

The rice mill.—Freetown Prison possesses the only power mill in the colony and all the rice used by the prisoners is treated here. From the contractors it is supplied as 'paddy' or rice in the husk which, before being fit for use, is cleaned by the mill, decorticated and polished partly to remove the pericarp. The end-products of milling are husk, powdered pericarp and cleaned rice, polished to any desired degree. There is a very large amount of dust in the atmosphere at this mill. This dust was collected from the walls and from the machine parts for analysis. On the whole, no sand was present among the fine floating particles. It is found chiefly in the deposit of pericarp dust in the mill and some with the husk deposit.

As many complaints of bronchitis, sore throat and gastritis are made by the prisoners who work the mill, they are supplied at the end of each shift with stimulating cough mixture. The expectorated sputum contained small particles of rice cortex with pericarp dust embedded in the desquamated pulmonary epithelial cells. Had silicosis been present, sand particles would have been present in these macrophage cells, but none were found. Phthisical sputa were not found.

The diet of the prisoners.—The diet recommended by Drs. Leitch and Watson which was drawn up expressly for its anti-beriberi value and its high calorie value is tabulated below:

Food-stuff	WEIGHT OF RATION	
	Ounces	
5-30 A.M.—Cocoa	$\frac{1}{2}$
Sugar	$\frac{1}{2}$
Wholemeal bread	2

10-0 A.M.—Foofoo (cooked)	..	24	
Beef (liver)	2	
or fish	2	
Greens (leaf)	2	
or fresh yeast	1	
and tomatoes	1	
Fresh yeast	2	
or tomatoes	2	
Onions	$\frac{1}{2}$	
Palm oil	1	
Cod-liver oil	1	
Pepper	3/80	
Salt	$\frac{1}{2}$	
Kaindah	a trace	
Fresh banana, orange, mango	1	
or pawpaw	12	
4-0 P.M.—Rice (raw)	2	
Beef or fish	4	
Yam or cocoa yam or sweet potato	2	
Ground nuts	2	
or dried beans	2	
or dried peas	1	
Tomatoes (fresh or tinned)	3/80	
Pepper	$\frac{1}{2}$	
Salt	a trace	
Kaindah	a trace cooked	
Rice, millings	in soup	
Fresh lime	a half	
Protein ..	3.26 oz.	Carbohydrate ..	17.2 oz.
Fat ..	3.4 oz.	Calories ..	3,347
			(increased later to over 3,500)

I have observed that strict adherence is being made to the new dietary. The quantities are measured with care and accuracy and, when recommended, liberal extra rations are allowed. Judged on accepted standards of vitamin value, there is no doubt but that the diet of the prisoners at Freetown Prison is probably the richest 'vitamin' diet in the colony, coupled with an intake of over 3,500 calories, suitable even for men doing heavy work in temperate zones. I am convinced that comparatively few of the general populace in Freetown, except the relatively well-to-do classes and the in-patients at Connaught Hospital, are as well fed. The prisoners have commented to me that they have never had such good and copious food in their lives.

The meals are supplied regularly, warmed and served from clean dishes in clean and tidy surroundings. Unfortunately, despite the fresh meat, greens, spinach, yeast, tomatoes, cod-liver oil, fresh fruit, sweet potatoes and ground nuts, beriberi continued to crop up in the prison.

Recently, since my appointment as medical officer in charge of Freetown Prison, I have had the opportunity of repeating some of the work done at Wilberforce Barracks and of securing new data along experimental lines.

One week before I took over the prison, the superintendent informed me that owing to shortage of supplies, he was obliged to revert to the remaining stock of old rice, containing a high percentage of discoloured grains. I concurred with his apprehension that he would surely have an outbreak of oedema. Within twelve days the complaints of pain in the chest with gastric troubles began and there were twenty-two cases of the disease noticed in the following fortnight, six of whom had to be admitted urgently to the hospital, where they made a rapid recovery. Six weeks after the issuing of the faulty rice, new grain was obtained and the disease completely disappeared in five days. The oedema subsided and no fresh notifications were made.

Outbreak of oedema.—The work was directed specially to enquire into the influence of old, 'sweated' and fungoid rice and a fortunate opportunity arose for the work. The superintendent of prisons had in the store a large stock of old rice, part of which had been issued to Wilberforce Barracks and to Kissy, and which, at

Freetown Prison, had been held responsible for the present epidemic. Although condemned it was still kept in storage. Up to December 1931, when the epidemic had been lasting from the time the supply of a mixture of new and old musty rice was delivered in 1931, there had been many reports of the sickness. About January 1932 new season's rice was obtained and this was milled, part-polished and issued to the prisoners. The epidemic subsided and the cases of oedema steadily cleared up.

The stock of new rice became exhausted, however, and the contractor delivered a large quantity of new season's rice, mixed with the old grain, which from its appearance had probably been in moist storage for a long period. Some of the rice was over one year old and it certainly was not new season's rice. This was milled and polished in the usual way. The rice contained a fair number of weevil-attacked grains and a large number of black fungoid grains and broken grains. I examined this rice and condemned it, but, for lack of other substances, part of it was fed to the prisoners. Seven days later there were complaints of constipation and pain in the precordial and epigastric regions and twelve days after the issue of this faulty rice there appeared four new cases of oedema. Three days later there were three other cases, all of whom were admitted to the prison hospital for observation. At the time Mr. Biddle assured me that if I wanted oedema cases I would be absolutely sure to get them after the issue of this diseased rice. His prophecy was borne out. On inspecting the men I found eight ambulatory cases distributed indiscriminately among the men (one tailor, one light labour, one mill, two stone breakers, three carriers). All complained of constipation. There was no evidence of nephritis but the general symptoms set out above were observed. They were diagnosed as cases of epidemic dropsy. During this small outbreak, I recommended that the boilings from rice (rice water) should be discarded and not added to soup or given to the prisoners in any form, coupled with the suggestion that the rice be more highly polished to remove the diseased pericarp. The epidemic has subsided and no new cases have been reported.

The observation that the rice be kept fairly highly polished, leaving about 15 per cent pericarp, was based on the laboratory findings of which details are given below. Mr. Biddle had noticed in a previous epidemic that there were fewer cases when the rice was fairly highly polished but no explanation of this point had been suggested.

The cases of oedema sent to the hospital for observation and treatment were taken along lines similar to those at Wilberforce Barracks Hospital. All the patients admitted displayed the characteristic signs and symptoms, including precordial pain and nausea, tachycardia, breathlessness on exertion, oedema of the legs with altered cutaneous sensation, deep muscular hyperaesthesia and constipation. The knee-jerks were present in all except one. One complained of his failing eyesight, with pain in the eyes, in which the intraorbital pressure was slightly raised. He cleared up after twenty-four days' treatment. The blood counts were variable, three being normal and three showing a slight hydramia.

The blood calcium was definitely lower than normal (10 mg. per 100 c.cm.) and amounted, on the average of four, to 7.6 mg. per 100 c.cm. In all of the cases, the pulse was increased in tension, without evidence of vascular disease, the blood pressure ranging from 156-168 mm. systolic and 94-102 mm. diastolic. With rest in bed these values fell to 130-134 mm. systolic and 80-84 mm. diastolic. One week after resumption of their tasks the pressures were still low and normal.

Two of the cases had liq. adrenalin hydrochloride (3 c.cm. of 1:1,000) injected experimentally into the oedematous zones of the legs. Localized diminution of the dropsy followed but no generalized improvement of the condition was the result.

In the treatment of these prisoners, two were given calcium lactate and purge and showed improvement

with return to labour in nineteen days. One was a case of myoendocarditis, with mitral stenosis and biliary cirrhosis. He was prescribed digitalin and, although an old case of 'heriberi' reported by Dr. Leitch, he was not considered as such for the purposes of this work. Two were treated with mist. alba (purge) and daily enemata. They were discharged after thirteen and fifteen days' treatment. Two were given mist. alba and an extra ration of meat. They were fit for discharge in twelve days and returned to duty.

The ambulatory cases.—Two men had been classified with the ambulatory subjects, who had all been put on the calcium and purge therapy but they did not show any improvement. It was considered that admission to the hospital was the best for them but, at that time, new rice came to hand and was issued to the men. Within five days these two subjects cleared up completely without recourse to admission. No cases terminated fatally in this epidemic.

Whether the lines of treatment follow calcium therapy or purgatives, it is considered that the therapeutic measures adopted against this disease must necessarily be entirely palliative. Not for one moment is it maintained that these measures can ever effectively compete with the simple expedient of altering the dietary to exclude deteriorated rice. In short I am strongly of the opinion that this is the crux of the entire condition. Granted that the disease, especially in the prison, can be effectively treated, the advocacy of prevention, is, I consider, the solution of the problem.

POST-MORTEM FINDINGS

Twenty-four cases were examined after death at Kissy Asylum and one at Connaught Hospital. They were almost all of a stereotyped nature, with oedema of the limbs, pericarditis with effusion and absence of nephritis. In detail, the necropsy in these cases gave the following results.

Externally, oedema, although constantly present in the legs, was elsewhere variable. Some cases had ascites and three had oedema of the face and neck. In some the abdomen was collapsed, in others distended with gas and ascitic fluid. Cutting into the oedematous subcutaneous tissues and muscles showed them to be sodden with serous exudate. The pleural sac contained variable amounts of clear serous fluid, varying in volume from two to twelve ounces. The lungs were adherent to the pleura, chiefly behind and some localized adherent patches were present anteriorly and at the mid-lateral right side (near the apex of the middle lobe). The lungs, themselves, in all cases were oedematous. The pericardium in all the subjects contained clear, free, serous fluid of straw colour. No bile staining, blood cells or blood staining was present in the fluids examined. The volume in the pericardial sac was variable from three to eighteen ounces. The heart showed great hypertrophy in all directions and the right auricle and ventricle were constantly dilated and filled with blood and a small amount of white ante-mortem clot. In all the cases, the valves were competent and revealed no vegetations or other signs of chronic impairment and there were no signs of endocarditis or aortitis. The heart muscle generally was considerably thickened and hypertrophic, without fatty degeneration or infiltration, but showing separation of its muscle fibres by oedema. Except when death had recently occurred, and where necropsy was performed in less than nine hours after death, the abdomen was distended with gas. In the peritoneal cavity of all cases free serous fluid was present varying in amount from a few ounces to two pints. All the cases showed 'pseudo-bile' staining of the abdominal fat. On examination this colour change proved to be due, not to haemolytic products, but to palm oil and no bile reaction could be obtained from this tissue. The distension of stomach and intestine was of variable amount and this was probably due to decomposition processes with gas formation. At the duodenum was found constantly areas of engorged tissues, with, in three cases, evidence of ankylostomiasis.

The mucosa of the stomach and upper part of the small intestine generally revealed this same type of engorgement and, in three subjects, petechial hæmorrhage of the duodenum was added to the hyperæmia. The liver was constantly but slightly enlarged and œdematous and showed evidence of venous congestion. In every autopsy the gallbladder was distended, smooth, glistening and of a dark green colour. There were no signs of adhesions and the surface of the gallbladder did not show the characteristic honeycomb markings of beriberi avitaminosis as described by Tull. The spleen was enlarged on an average to one inch below the costal margin and it was œdematous. The kidneys were of normal size, pale and œdematous, with normal capsule. There was no evidence of nephritis. The suprarenal bodies in five cases were somewhat enlarged and one contained evidence of infarction. No gross changes were observed in the nervous tissues, the bones or the pancreas.

Rice analysis.—The analyses of the rice for general purposes were estimations of carbohydrate, protein, fat, water, ash, cellulose, phosphorus and amino-soluble nitrogen. They were conducted along the well-known standard methods.

Chemical analysis.—The analysis of the rice, with special reference to the husk, was not deemed necessary for inclusion in this report because in the milling this article is a waste product and is not used for eating purposes. Attention was directed chiefly to the rice grain and the pericarp, with special emphasis on the type of rice which was known to produce the disease, when fed to human beings.

The colony's new season's rice was employed at first as a standard for comparison of the protein, carbohydrate and fat content and caloric value, but it was suspected that these values would not shed much light on the causal factor of the disease and, in the light of biochemical work done on the decomposition products of the protein layers, I feel sure that the general analysis of the food-stuff, although interesting, is not of paramount importance.

Beriberi standards.—Among the conclusions of Vedder and Feliciano (Philippine Islands experiments) are to be found chemical standards for estimating the anti-neuritic (anti-beriberi) value of a rice in the absence of any direct method of obtaining the exact amount of anti-beriberi vitamin. These standards include:

(a) Any rice having 1.77 per cent P_2O_5 plus fat, but not less than 0.4 per cent P_2O_5 .

(b) Any rice not having less than 0.5 per cent P_2O_5 with at least 75 per cent of the external layers of the grain.

Sierra Leone rice comes well up to these standards with:

(a) P_2O_5 —0.57 per cent plus fat $1.84 = 2.41$ per cent.
(b) P_2O_5 $\quad \quad \quad = 0.57$ per cent.

and, according to their accepted theories, there is little risk of development of true beriberi, when the staple diet consists of this colony's rice. The rice has a high anti-neuritic value, is well balanced in terms of protein, carbohydrate, and fat and has an energy value of sixteen hundred and fifty calories per pound.

Diseased rice.—The chemical work was chiefly directed against the 'faulty' rice, which, from observations at Freetown Prison and Wilberforce Barracks, was known to be associated with the œdema. When this rice was replaced by new season's rice or was specially treated in cooking, the œdema subsided and no new cases appeared. This rice was supplied as husk rice (paddy) and milled in the usual way before distribution to the various consumers. In this substance attention was particularly directed to the end-products, namely, the rice and the pericarp dust, both of which were submitted to chemical analysis in the usual way, the husk, as before, being discarded.

Fungoid rice polished 40 per cent pericarp

	Percentage
Carbohydrate	77.24
Cellulose	0.74
Fat	0.46
Protein	8.46
Water	12.32
Ash	0.78
P_2O_5	0.21
Soluble nitrogen	0.25

The faulty rice was milled and partly polished (40 per cent pericarp). The odour was slightly musty. Mycelial hyphæ and spores were seen on the surface of the grains. It was a mixture of white and discoloured grains (yellow, brown, black) up to forty per cent. Evidence of weevil activity was noticed in the bored grain, and weevils themselves (identified as *Calandra oryzae*, *Calandra granaria*, *Tribolium ferrugineum* and *Silvanus advena*) being present together with rice bugs and maggots. Fully thirty-two per cent of the grain was bored and showed evidence of larvæ. The rice had a relatively high percentage of broken grains, amounting to thirty-seven per cent. On an average, the amount of germ was low, nine per cent of the grains had all the germ, forty-four per cent contained a portion and in the remainder the germ had been completely removed either by milling or by parasite activity. The presence of fungoid grain was noted and especially in the discoloured grain could be seen mycelial threads, which were not so common on the sound white grains.

There is at once apparent a deviation from the standard rice in terms of fat, P_2O_5 and amino-soluble nitrogen; the other constituents being practically unaltered. The combined deviation was thought to be due to parasite activity in the old rice. With this aspect in view, considerable attention was given to the diseased rice products and later to the pharmacological action on animals of extracts of this rice.

Diseased rice polishings.—The pericarp dust was subjected to the same type of analysis. This dust is slightly acid in reaction, musty to smell and, when inhaled, causes violent sneezing and coughing. The prisoners employed in the mill are given expectorant cough mixture at the end of each shift to relieve the sensation of oppression it causes, which is worse when the old rice is milled. Some of the men appeared to develop asthmatical attacks when they went on the job at first and in the morning when work commenced. The dust floating about from the mill does not contain free sand in any large volume, even at the outlet of the machines, and it does not cause silicosis; examination of sputa for this condition was entirely negative for the presence of sand and *B. tuberculosis*, although vegetable fibres are quite commonly embedded in and lying upon large desquamated macrophage cells from the pulmonary epithelium. This pericarp dust was subjected to the same type of analysis before which it was entirely freed from sand and from a large amount of adventitious cellulose fibre derived from the husk.

Certain aspects are immediately obvious; the increased water content, always generally associated with fungoid activity, together with the diminution of fat and phosphorus and the big increase in the soluble nitrogen into the nature of which obviously it appeared enquiry may be made with profit.

Effect of washing rice.—Before proceeding to submit the work done on extracts of the faulty rice and of the pericarp, it is considered advisable at this point to state the effect on the grain of washing. From now onward, unless otherwise stated, it will be understood that the rice mentioned is the deteriorated grain, which was known from experience to be faulty and to produce œdema when eaten and the terms bad and faulty rice will be discontinued.

(a) **Rice.**—Apart from removing sand, adventitious insects, weevils, and dust, washing with water has a definite effect on the rice itself. The grain is washed

in cold (85°F.) running water for ten minutes, as the equivalent of the native method in which the washing is done in large pans with several changes of water. Thereafter, the grain is sun-dried and analysed in the usual way. The analyses are tabulated below:

	Before washing Per cent	After washing Per cent
Carbohydrate ..	77.24	76.97
Cellulose ..	0.71	0.71
Protein ..	8.46	8.18
Fat ..	0.46	0.46
Water ..	12.32	12.89
Ash ..	0.78	0.76
P ₂ O ₅ ..	0.21	0.18
Soluble nitrogen ..	0.25	0.16

Very little change takes place in the nutritional aspect as expressed by the calorie value. Carbohydrate, fat and protein are more or less the same, but there is a definite, but slight, loss in the phosphorus estimate, amounting to 14.28 per cent. I consider, however, that apart from obvious impurities soluble toxins, expressed in terms of soluble nitrogen, are definitely lessened by the washing. Although the soluble nitrogen quota is reduced considerably from 0.25 per cent to 0.16 per cent, it is apparent that an appreciable amount remains, even after the thirty-six per cent loss. The phosphorus loss has been considered a loss in terms of vitamin B. McCarrison and Norris proved that any rice originally shown to be beriberi-preventing may, with removal of a large percentage of P₂O₅ by prolonged washing, be altered into a "non-beriberi" rice, but, although this holds for .. it does not do so for the edema under consideration, where the vitamin B content is more than adequate. Some other causal agency was held to be at work.

(b) *Pericarp*.—Results of a similar nature were obtained with pericarp dust. The rice polishings were washed in cold running water for ten minutes, squeezed dry, spread out in the sun and dried for two days. As in the case of the rice, no form of artificial heat or of desiccation was employed.

Fungoid pericarp dust

	Before washing Per cent	Sun-dried. After washing Per cent
Carbohydrate ..	48.18	48.92
Cellulose ..	3.68	3.66
Protein ..	11.21	10.98
Fat ..	14.74	14.70
Ash ..	8.33	7.02
Water ..	13.86	14.72
P ₂ O ₅ ..	3.61	2.48
Soluble nitrogen ..	0.44	0.29

The results are similar to those obtained after treating rice with water. Washing does not affect, to any appreciable degree, the value of protein, carbohydrate or fat, but the main influence is shown in the soluble nitrogen and phosphorus content. In the former there is a reduction of 34.09 per cent and in the phosphorus value washing lowers the content by 31.30 per cent.

Washing with hot water.—The influence of washing was studied in terms of cooking. The rice is brought to boiling point and the rice water decanted and rejected. It is equivalent to considering that the rice undergoes part of the normal cooking process when it is washed in boiling water.

Two experiments were made:

(a) in which the rice was thrown into boiling water;

(b) in which the rice was put in cold water and heated to boiling point.

In both, after boiling had continued for three minutes, the water was decanted and strained off and the rice dried in the sun for two days. The usual analyses were made on this final dry rice product.

	(a) Boiling water Per cent	(b) Cold water to boiling Per cent	Unboiled and unwashed
Carbohydrate ..	75.53	72.65	77.24
Cellulose ..	0.62	0.60	0.74
Protein ..	7.88	6.46	8.46
Fat ..	0.34	0.22	0.46
Water ..	16.93	19.47	12.32
Ash ..	0.70	0.60	0.78
P ₂ O ₅ ..	0.14	0.12	0.21
Soluble nitrogen ..	0.02	0.00	0.25

It is obvious again that, with special reference to all the proximate principles, the energy value of the rice is not seriously impaired by this treatment, when it has been boiled and the rice water rejected. This value is, undoubtedly, not so greatly affected by throwing the rice into boiling water for a few minutes, as when the rice is brought slowly to boiling point, because then the degree of imbibition of water is less with correspondingly higher value of protein, carbohydrate and fat.

By either method, although the loss is fairly considerable (33.3 per cent and 42 per cent), the phosphorus element is not by any means all removed by short immersion in boiling water. Soluble nitrogen, however, shows results which are to be expected from the method of its estimation. The reduction amounts to 92 per cent of the total original soluble nitrogen method (a) and to complete absence in (b) when the rice water is brought to boiling point 'from the cold'.

Results of a similar nature were obtained by extracting the pericarp dust employing these same methods; that is, a large reduction in the P₂O₅ content and in the soluble nitrogen. However, as this is a waste product, it is not deemed essential to submit the results.

For the purpose of this research the intimate analyses of the rice washings are not given here, as this aspect is more or less of academic interest.

Culture of grains.—Inspection of the rice revealed, as was mentioned above, the presence of discoloured grains, mixed with normal white rice. These grains were divided into two groups, yellow and black, for culture experiments and special analysis. The discoloured grains were, in all cases, found to be dead; microscopically, erosion of the starch was in progress and the grains were contaminated with mycelial septate filaments. Samples of white, yellow and black grains were surface sterilized and put in a warm moist chamber for thirty-two days. All the rice samples increased in water content. The black grain became sodden and soft. Its soluble nitrogen content increased from 0.59 per cent to 0.85 per cent, with very slight loss in the P₂O₅ due to imbibition of water by the grain. The yellow grain turned to a dark brown colour, almost black, absorbed water but it did not become sodden and soft like the black variety. The soluble nitrogen increased also in this case from 0.28 per cent to 0.39 per cent, again with slight alteration in P₂O₅. The white grain, like the other two groups, developed a heavy growth of mould, but the colour change was not so marked. Some of the grain (3 per cent) became brown and some (35 per cent) was stained yellow, but the rest was more or less unaltered in colour, being, if anything, of a greyish tint. The soluble nitrogen increased in this sample, as in the others, from 0.03 per cent to 0.09 per cent. It was assumed that these conditions, although not by any means similar to normal storage, would reproduce rapidly in the grain that which occurs in storage in the country over a long period of time. Under conditions of moist warmth, with the possibility of increased temperature by fermentative processes in a large mass of grain, heat is generated and cannot escape readily from the decomposing mass. In this way, with heat and humidity, the growth of fungi and of other organisms is exceptionally rapid, with the net outcome that decomposition proceeds apace.

Preliminary work with extracts.—The first extracts made of the rice were evaporated *in vacuo* to small bulk without attention to percentage concentration. They were sterilized, without heating, and injected subcutaneously into normal subjects, and to oedematous cases. Localized oedema resulted, associated with a marked reaction. Similar extracts were scratched into the skin and there was produced a flat raised wheal with white centre due to vasoconstriction together with a surrounding zone of slight erythema, such as is obtained when histamine and allied substances are injected intradermally. Subsequently from the rice polishings, both unfermented and fermented, raw and cooked, extracts were made and tested chemically and biologically.

Chemical assay of extracts.—The reactions were suggestive of the histamine group of substances, obviously, therefore, the chemical tests, in view of these reactions, were directed to a study of the iminazole derivatives in the extracts, and one of the most delicate chemical tests for this group was employed. The rose-pink colour struck by alkaline sodium diazobenzene-sulphonate is given by dilutions of histamine even to 1:10,000 but this reaction is not, however, absolutely characteristic of histamine alone. It may be given by any iminazole derivative containing a free amino group, together with a replaceable group in one of the two, four or five positions, with the exception that no colour is given should a nitro-carboxyalkyl or carboxyanilide group occupy the four or five positions and it may be obtained in the presence of bases in the arginine, purine and tyrosine groups. A negative result is taken to show that histamine is absent, or, if present, only in infinitesimal quantities, but a positive reaction shows that either it or the allied bases may be present. The most reliable test is obtained by biological assay, employing intradermal tests and the effect of the substance on the isolated uterus, together with the persistence of these effects after alkali hydrolysis.

Extracts of rice.—The extracting media employed were all found to give negative results when used as controls, either chemically or biologically, and the same weight (100 grams) of material was used from which the extracts were made, together with constant volumes of the various extracting agents.

All the extracts made from new rice gave entirely negative reactions to the histamine intradermal tests. Similar results were obtained from rice that had been—

(a) put in cold water and heated to boiling;

(b) immersed for a few minutes in boiling water.

Dry faulty rice, however, gave positive results in most cases. In the presence of increased proportions of discoloured grain, the reactions were increased in intensity. The polishings from the faulty rice yielded reactions of a very definite type. It was, however, when employing the mouldy grain and fermented pericarp dust that the strongest effects were obtained, especially from rice with a high percentage of black mouldy grain showing putrefactive changes.

There was obtained a definite increase in these histamine bodies when the discoloured grains were kept for a period in the warm moist chamber. The intensity of the reactions was greatest with black grain, less with yellow and from the white rice no reaction could be obtained.

Feeding experiments.—Feeding experiments were conducted at Connaught Hospital and at Wilberforce, employing fowls and guinea-pigs. In the earlier observations, four fowls were used. Two were fed on washed [method (b)] grain and two had unwashed rice. These experimental animals were allowed to roam about as they pleased and to eat such green material as they thought fit. After five weeks, one of the latter died and was found to have congested liver and pericarditis with effusion. The lungs were slightly engorged. Its partner on the unwashed diet was killed one week later and found to have slight pericardial effusion with engorged crop and hyperæmia of the stomach and upper intestine. At the same time the other pair on the

washed rice were killed and found to be perfectly healthy.

Guinea-pigs were useless for feeding with dry material because they refused flatly to eat the rice. This was, to a large extent, overcome by making an extract of the grain, mixing this into bread and feeding the wet product to the animals which ate the mass avidly. The animals thrived on the extract from standard rice and from musty rice which had been washed. When killed the carcasses were those of healthy animals.

Extracts from dry, faulty rice and pericarp did not kill the animals immediately but they went off their food after fifteen days and refused to take the quantity they consumed at first. One animal died after twenty-one days on this food (bread soaked in aqueous extract of rice). It was found to have slight oedema of the lungs and acute gastro-enteritis. Three guinea-pigs were fed with greens, grass (their usual food) and with the addition of bread soaked in an extract from the fermented discoloured rice grains. Ten days later the first animal died; its two companions succumbed the next day. The post-mortem examinations again showed oedema of the lungs with gastro-enteritis, engorged intestine and hæmorrhages at the upper area of the duodenum. These animals apparently suffered intense pain, as they were exceptionally tender to touch, listless and breathless. They became very weak and scarcely had the energy to run away when approached.

Inoculation.—To ensure absence of bacteria and yeast spores, the extracts were freshly made and sterilized, without heat, which might have altered the toxins. Guinea-pigs were used into whose flanks the extracts were given subcutaneously only.

The extracts of new season's rice caused no sickness in the experimental animals. No ulcers or abscesses were produced at the site of inoculation. The animals were injected daily for eight days and found to be normal when killed.

Inoculation of sterile extracts of the old fungoid rice made the animals highly excitable five minutes after injection but in half an hour this passed off. Three days after inoculation commenced the animals became listless and refused to take their food. Of the three animals used, two died after five days of injection treatment (an injection of one c.c.m. extract being given daily) and the remaining one died in seven days. All showed similar pathological changes. Around the sites of injections were zones of hyperæmia but no pus or septic condition was observed. The heart was congested, the lungs engorged and distended with blood, and there were punctate hæmorrhages in the small intestine.

An extract made of pericarp dust that had been kept under moist conditions was sterilized and inoculated. This animal died one half hour after. Autopsy revealed hyperæmia around the site of inoculation. The lungs were fully distended but not oedematous. The right heart was dilated, the intestine gorged and the stomach in spasm. Entirely negative results were obtained from the injection of sterile extracts of washed rice.

The contraction of the isolated involuntary muscle was studied in a roughly constructed piece of apparatus, using preparations of the uterus and intestinal muscle of the guinea-pig. The preparation passed into powerful contraction on exposure to an extract of the faulty pericarp dust. This contraction was not, in any way, counteracted by the addition of atropine.

Urine analysis from patients.—With the exception of two suspected cases of oedema in whose urine was found albumin with granular casts, no obvious pathological changes of the usual types were found.

The urine in general was pale straw-coloured, very slightly acid, having a specific gravity of 1022. When passed, it was free from sediment and mucus clouding but, on standing till cold, earthy phosphates were deposited. The usual ammoniacal phosphates appeared on allowing it to stand for twenty-four hours. In almost all the cases the output of an excessive amount

of the earthy phosphates was commented upon and considered, to be not clinically normal. The buffer action of phosphate in the blood is considerably higher than that of sodium bicarbonate, from which observation it is suggested that the increased urinary phosphate value represents the end-product of a successful attempt by the alkali reserve to neutralize the acidity produced in the toxæmia. The absence of albumin and the presence of these phosphates tend to show that the renal mechanism in this disease is not grossly abnormal; an observation confirmed at the post-mortem findings.

Only in the severe cases was the indoxyl reaction obtained to a marked degree but almost all the specimens of urine from the patients gave a positive test indicative of indole b. acetic acid. Albumin, blood sugar, diacetic acid, acetone bodies and bile products were not observed to be present in pathological amounts in these urines.

Fæces analysis.—Apart from the presence of a trace of occult blood in seven cases, the analysis of the fæces did not shed light on the problem.

Blood calcium.—The recognized methods of analysing the amount of calcium in the blood were employed in a study of some of the prison cases. On an average, the results showed calcium deficiency (7.6 mg. per 100 c.cm.) which is a definite deviation from the accepted normal value of 10 mg. per 100 c.cm. The work along these lines continues.

In the main, I have submitted the results of the observations and findings from the biological aspect of the research, without, in any way, attempting to give every detail of the technique employed, which followed generally the standard methods in use.

DISCUSSION OF THE PROBLEM

The disease most commonly puts in an appearance when old and new rice crops have been mixed and Mr. Biddle has noticed that the disease breaks out in the year succeeding that of a bumper crop, with large stocks of old rice left in the dealer's hands after the new crop comes in. The new crop contains a much greater proportion of moisture. In these circumstances, mixing appears to favour decomposition. Fungi and the dormant spores of fungi have improved facilities for growth on account of the increased moisture content of the mixed mass and of the heat engendered, as in some cases of so-called spontaneous combustion by the fermentative changes in a moist heap. Storage during a rainy season appears to be ideal for such organismal activity because of the heat and the high relative humidity. These, it is maintained, are the attributes that make the problem serious in this colony. It is held that the rice becomes highly toxic if it is a mixture of old and new crops and is stored in conditions that encourage destructive attacks by fungoid and other organisms. If mixing of crops is permitted there is absolutely no guarantee but that these outbreaks of fatal epidemic dropsy will be repeated and I make bold to assert that this is one of the essential factors determining the control of disease. In addition to the effect of mixing old and new crops, there is accumulating evidence that similar and rapid destruction occurs when new season's crop is kept in wet storage, or stored in an imperfectly dried condition. It has been observed, as in other tropical and sub-tropical countries, that the disease appears when grain is eaten after prolonged storage under moist warm conditions.

That there are changes in the intimate chemical structure of the rice is seen from the change in soluble nitrogen and phosphorus content. These are associated with putrefactive changes. With an increasing value in the soluble nitrogen content, there is found evidence of increasing destructive changes. That the destructive change results in the production of soluble toxic substances has, I think, been established clinically, biochemically and physiologically, when extracts of this rice are made and utilized either for animal inoculation or for chemical study. Apart from the observations made on human subjects and in the field of clinical

medicine, there are the concomitant results of the biological experimentation of which recapitulation is unnecessary. The toxic element is soluble in water, a point demonstrated by the beneficial effects of washing the rice and rejecting the rice water resulting in the almost entire removal of a soluble toxin whose nature is, essentially, that of the histamine-tyramine groups. It has been shown that the soluble nitrogen factor in relation to total nitrogen may be considered a reasonably good index of the toxicity of the food-stuff.

When new rice is given to patients suffering from the œdema under review, the disease rapidly clears. In a way this may be the outcome of several factors. There is the resistant state of the living rice germ to disease, associated with the non-destruction of the protein aleurone layer and there is the factor of time, as new season's rice has not been subjected to prolonged bacterial and fungoid activity. Consequently, one expects even from this last aspect little, if any, putrefactive changes.

When considered purely as a disease due to the lack of vitamin B, it is difficult to understand why, with the superabundant diet issued at the Freetown Prison, beriberi should continue to be present, and also, if its nature is essentially one of 'avitaminosis', why the disease should be of so protracted a type, when additional accessory food substances almost to excess are exhibited. On the other hand, the aspect that this disease of œdema is due to toxic absorption, finds support on a number of points.

Conclusion

œdema at the Freetown Prison, Wilberforce Barracks, and Kissy Asylum is not that of beriberi (avitaminosis) but it is akin to epidemic dropsy. It is not associated with any lack of or diminution of accessory food substances, as vitamin 'B', which has been supplied in copious amounts to the inmates of these institutions, nor is it allied with protein starvation. The disease is essentially one of auto-intoxication, due to absorption of highly poisonous nitrogenous putrefactive products, engendered in old rice by the activity of organisms acting in hot and moist conditions and producing bodies of a nature allied to the histamine-tyramine groups. The toxic substances are water soluble, especially in hot water, and they are capable of withstanding boiling water, without considerable alteration of their poisonous principles. This last observation is important, as recommendations have been made in former epidemics that the rice water should be saved and added to the soup.

The disease-producing grain has a musty odour and, generally with discoloration, displays the presence of decomposition and of fungoid activity. Consumption of such food-stuffs is fraught with great danger, resulting, *inter alia*, in the rapid onset of œdema of an extremely fatal nature.

Rice forms the staple food of the colony and owing to a rapid extension of swamp-rice farming during the past three years an export trade in it is anticipated. œdema, therefore, becomes a matter of serious concern, especially, where it is known that apart from its incapacitating effects this condition is attended by a very high mortality among consumers of rice which has been permitted to become decomposed.

Correspondence

THE FORMULA OF ATEBRIN

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—The anti-malarial remedy Atebrin, which was synthesized in the scientific laboratories of Bayer-Meister Lucius, Elberfeld, by the chemists Mietzsch and Mauss under the direction of Professors Hoerlein and Schulemann has, according to information received from the said laboratories, the chemical composition

of 'Dichlorhydrate of 2 methoxy-6-chlor-9-alpha-diaethyl-amino-delta-methyl-pentyl-amino-acridin', and has the following constitutional formula:

Further details can be obtained from a paper by Mietzsch and Mauss in the *Klinische Wochenschrift* of 19th August, 1933.

Yours,
O. URCHS.

THE DOSAGE OF PLASMOCHIN

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR.—The importers of the French anti-malarial remedy Gametoxyl have lately issued an advertisement pamphlet giving a résumé of a paper by Dr. E. Charron, Paris, on anti-malarial preparations. The author compares at the end of his paper Plasmochin Compound with Gametoxyl, referring particularly to the time of treatment and the amount of medicament required for a complete anti-malarial treatment.

In his statement he mentions that the *daily* dose of Plasmochin Compound amounts to 12 to 16 tablets of the drug and that the total number of tablets required for a complete treatment lasting six weeks is 328 tablets.

Although the above dosage refers to our old, discarded tablets containing $\frac{1}{16}$ th grain Plasmochin and $\frac{1}{16}$ th grain quinine sulphate, this dosage would be decidedly dangerous, and we should be greatly obliged if you would issue a warning in your esteemed journal against using the dosage mentioned by this writer. Physicians are strongly advised to use only the dosage recommended in the authentic medical literature and the official pamphlets of our firm, who can only hold themselves responsible for the dosage recommended by them.

Thanking you in advance,
We beg to remain,

Sir,
Yours faithfully,
HAVERO TRADING CO., LTD.

SERVANTS OF INDIA SOCIETY FLOOD RELIEF FUND

To the Editor, THE INDIAN MEDICAL GAZETTE

DEAR SIR,—The heavy losses suffered by the people of Cuttack and Puri Districts owing to heavy floods and breaches in the several embankments in the said areas this month have called for sympathy from all quarters. Hundreds of homes have been swept away, thousands of people are now without shelter. Their agricultural lands have been mostly covered with sand. They are without much clothing. Immediate and instant relief will be needed for them. Government has also admitted this fact in their communique published from Ranchi on 16th August. About 40 by 50 square miles have been devastated.

I, therefore, appeal to you to help these distressed people through me. I am a public worker of that part

of the country and a life-member of the Servants of India Society. I have been doing this sort of relief work for the last 15 years in U. P., in Bengal and B. and O. I worked in Garhwal Famine Relief in 1918, in East Bengal Cyclone Relief in 1919, in Puri Famine Relief in 1920, in the Vaitarani Flood Relief in the Kconjhar State in 1927.

May I hope, therefore, that you will be pleased to entrust your charity to me.

Yours, etc.,
L. M. SAHU, M.A.,
Member.

SERVANTS OF INDIA SOCIETY,
CUTTACK,
30th August, 1933.

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL A. J. H. RUSSELL, C.B.E., Officiating Deputy Director-General, Indian Medical Service, is confirmed in that appointment, with effect from the 28th July, 1933.

Lieutenant-Colonel C. Newton-Davis, M.C., Officer Commanding, Indian Military Hospital, Delhi, is appointed to officiate as Chief Medical Officer and Civil Surgeon, Delhi, in addition to his own duties, during the absence of Lieutenant-Colonel Wilson on leave.

Lieutenant-Colonel T. C. Boyd, on return from leave ex-India, has been re-appointed as Principal, Medical College, and Superintendent, Medical College Hospitals, Calcutta, with effect from the 6th August, 1933.

Lieutenant-Colonel K. S. Thakur, Civil Surgeon, Howrah, is appointed as Civil Surgeon, 24-Parganas, during the absence, on leave, of Lieutenant-Colonel A. Denham White.

The services of Lieutenant-Colonel J. Findlay are placed permanently at the disposal of the Government of Burma, with effect from the 3rd February, 1925, for employment in the Burma Jail Department.

The services of Major J. E. Ainsley are placed permanently at the disposal of the Government of the Central Provinces, with effect from the 17th August, 1933.

The services of Major A. J. D'Souza, M.C., late Senior Medical Officer, Port Blair, are replaced at the disposal of the Army Department, with effect from the 26th November, 1933.

The services of Captain J. C. Drummond are temporarily placed at the disposal of the Government of India, Army Department, with effect from the 26th August, 1933.

Captain A. Tait, Officiating Superintendent, Central Mental Hospital, Yeravda, was granted leave on average pay from 22nd July, 1933, to 22nd August, 1933 (both days inclusive). His services were replaced at the disposal of the Government of India, with effect from 23rd August, 1933.

The services of Captain H. S. Waters, Officiating Resident Medical Officer, St. George's Hospital, Bombay, have been replaced at the disposal of the Government of India, with effect from the 24th August, 1933.

The services of Captain A. M. Sheridan are placed temporarily at the disposal of the Chief Commissioner of Coorg for appointment as Civil Surgeon, Coorg, with effect from the 1st September, 1933.

To be Lieutenants (on probation), 1st August, 1933

F. W. Allinson, with seniority 1st August, 1932.
F. R. Cawthorn, with seniority 1st August, 1932.
F. V. Stonham.
J. F. J. Doyle.
J. M. Matthew.
W. B. Stiver.
J. J. Barton.
Leo Feinholts.

SOME COUNTRY BEERS OF INDIA

By R. N. CHOPRA, M.A., M.D. (Cantab.)

LIEUTENANT-COLONEL, I.M.S.

and

GURBAKSH SINGH CHOPRA, M.B., B.S.

School of Tropical Medicine, Calcutta

(Drug Addiction Inquiry, I. R. F. A. Series No. 18)

Introduction.—All races whether civilized or savage have made use of intoxicating drinks of some kind from time immemorial. Modern research has established the fact that alcoholic beverages were prepared from cereals by the Babylonians about 4,000 B.C. and ancient explorers have dilated upon the wonderful skill of man which enabled him to turn barley into wine. Primitive man in his progress towards civilization first developed the art of agriculture and there appears to be little doubt that the cultivation of barley preceded that of wheat. The use of these cereals in bread-making was intimately related to the manufacture of beer, and in ancient Egypt and Babylon bakers and brewers prepared bread and beer which were consumed by all classes of the community. Various kinds of beers were brewed in Egypt from different cereals and their use was intimately connected with the sacrificial rites performed in those days. The Egyptians taught the art of brewing to the Jews and Greeks, the latter transmitting their knowledge to the Romans. There is evidence to show that the Romans made ample use of this knowledge because beer was served to the armies of Julius Caesar as a ration. The beers of early days were flavoured with wormseed, ground-ivy, pine, willow-bark, etc.; hops only came into use very much later.

The ancient Aryan invaders of India were also well versed in the art of brewing drinks and earlier than 2,000 B.C. used a beverage called 'soma'. The exact nature of the 'soma' of the Vedic period is still wrapped in mystery and there are about a dozen different plants whose juice is said to have been the 'soma' so much talked about in Sanskrit literature. Hemp and ephedra figured in this list. According to Professor Max Muller 'soma' was probably a kind of fermented liquor. The 'soma' or 'homa' plant (*Sarcostemma* of botanists) was imported into India from the north by the Mongolian Tartar races. When properly squeezed it yielded a juice which was allowed to ferment and being mixed with honey it produced an exhilarating and intoxicating drink. According to Ray (1906) three kinds of liquors were known in the time of Manu, viz, *gauri* prepared from molasses, *madvi* from the sweet flowers of *Bassia latifolia* and *paishiti* from rice and barley cakes. Of these

paishiti was reckoned as the most common. The *suras* were included under the generic term *madya* meaning every kind of alcoholic drink. The word *kohala* occurs in Susruta a Sanskrit medical treatise written in the 5th century A.D., in which it means an alcoholic beverage made from powdered barley. Another word *jagala* also occurs in Susruta and in much earlier works such as Charaka, etc., in which *kohala* is not mentioned. *Jagala* was a kind of rice beer. It is probable that the English 'alcohol' and the Arabic 'aleohol' have the same origin as *kohala*. It would therefore appear that the art of fermenting starch and saccharine substances was understood and practised in India. The aboriginal races of India in all probability learnt the art of brewing from the Aryan invaders and from time immemorial they have been preparing and using such beverages. Some of these beverages are being used at the present time and in this paper we propose to give an account of the results of a survey of their incidence and the effects they produce.

Certain drinks and beverages commonly used in many parts of the Himalayas appear to be similar to those commonly used by Mongolian races. Some of these preparations resemble *shamshu* and *saki* used in China and Japan. The reason for this is not far to seek for the Mongolian stock gradually invaded India from the north-east, and evidence of this invasion still exists in the Mongolian characteristics of the Himalayan races at the present time. The use of such beverages in these parts is therefore easily understood and often they appear to form an important part of the dietary of the people. These liquors were also drunk by some of the aboriginal races driven southwards by the Aryan invaders, their use being essentially confined to the poorer classes. The materials used, the method of their preparation, and their general appearance, smell and taste are such as to be repulsive to the more refined races of Aryan stock, and among the latter only people belonging to the lowest ranks of society resort to these drinks.

Extent of use of Indian beers.—Our enquiries in the field show that country beers are drunk by Sonthals, Kols, Bhumijs, Bhutiyas, Mundas, Dosads and Oraons. The other tribes using these liquors are Haris, Bagdes, Domes, Moochis, Chandals, Jolas, Kaibartas, Mals and Dhangars. In the Darjeeling district, *marua* beer is universally drunk by Bhutiyas, Lupchas and other hill tribes. All the hill tribes in Assam, such as the Khasis, Lushis, Nagas, etc., use these beers as a common article of their dietary. The liquors are drunk equally both by males and females except that the Sonthal women sometimes object to the liquors as sold by licensed vendors and only take what is brewed at home. As far as our information goes no Hindus or Mohammedans of the higher classes take these beers.

sleeve enables the tube to be raised and lowered absolutely smoothly and uniformly, so that even with the highest magnifications the image remains perfectly steady. This also means great stability of the fine-adjustment mechanism, an important point when a microscope is in constant use.

This novel microscope, owing to its small size (3 in. by 7 in.) and trifling weight (2½ lb.), should be peculiarly suitable for export.

The Hensoldt firm has appointed The Scientific Apparatus and Chemical Works, Ltd., Agra (U. P.), as their sole agents in India from whom the particulars and prices may be obtained.

TONSIL-HOLDING FORCEPS

By T. H. R. McKIERNAN, M.B., B.Ch.

THIS forceps illustrated herewith is nothing more than a modification of Duval's peritoneum pattern. The blades are curved to almost a right angle with the handle, so that when the tonsil is grasped there is ample room for the use of scissors or other instruments to carry out the enucleation. It has some advantages inasmuch that the tonsil is held firmly and may be drawn well out of the tonsillar fossa. No damage is

inflicted on the tonsil and the view of the operation field is not restricted. It is extremely light and in

practice it works well. It would be advisable to have a smaller size for use with children.

Messrs. Down Bros. have carried out my suggestions in making this instrument.

ADEXOLIN CAPSULES

EACH 3-minim capsule is precisely standardized to contain the vitamins A and D equivalent of 10 grams of high grade cod-liver oil. This preparation, which has been available to the medical profession since 1928, is valuable in the prophylaxis and treatment of infective processes, the high content of vitamin A serving to maintain the anatomical and functional integrity of the epithelial tissues, thus preventing the invasion of underlying tissues by pathogenic organisms, and the vitamin D reinforcing this 'anti-infective' action and at the same time maintaining an optimal concentration of calcium and phosphorus in the blood serum. The vitamin A is incorporated in the form of a special solution concentrated from the richest natural sources; the vitamin D is present in the form of the pure crystalline product (calciferol G. L.). The normal prophylactic dose for adults is one capsule a day—for example, during pregnancy, or for the prevention of such infective illnesses as influenza and the common cold. The dose for such treatment or for aborting infection may be much larger, up to a capsule every waking hour.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

indulge in polyandry. In the plains of the Punjab, Sindh, Rajputana and the western districts of the United Provinces beer is not used, its place being taken by such drugs as hemp preparations and opium.

Bengal and Bihar.—*Pachwai* is the universal drink of the aboriginal tribes such as Sonthals and Bhils inhabiting the Chota Nagpur hills which comprise the districts of Ranchi, Hazaribagh, one division of Bhagalpur and the Sonthal Parganas. In Patna, Gaya, Monghyr and Darbhanga, *tari* is largely used. On account of the migration of the inhabitants to the adjoining plain districts of Bengal, namely Burdwan, Birbhum, Bankura, Murshidabad, etc., the use of *pachwai* has spread all over this province especially in the western and northern districts which adjoin the Chota Nagpur hills and the Himalayas. In the northern and eastern parts of Bengal comprising the Darjeeling district, Sikkim and Bhutan borders, the use of a different kind of beer called *marua* is in vogue. In these districts home-brewing is permitted and, in addition, licences for retail sale are sold by auction to the highest bidder. Country beers are little used in Eastern Bengal, except in the two districts of Jalpaiguri and Malda.

Assam.—In Assam the consumption of beverages such as *zu*, *madh* and *laopani* is universal and they are the national beverages of the aboriginal hill tribes. They have also been adopted by some of the lower strata of Indian working classes such as the tea-garden coolies. Consumption of these beers is almost universal and extends along the border of the Himalayas right up to the Shan States in Burma. Little control appears to be exercised over their production in these areas. Further east there is the *marua* used in Sikkim and the neighbouring hills and *zu* used by the Nagas. Some of these tribes never drink water but always take these beers.

Central Provinces, Bombay and Southern India.—Similar beverages are also used in central and southern India in the hilly country stretching from Orissa to Godavari (non-regulated tracts of Madras Presidency). In larger portions of the Madras and Bombay Presidencies, the use of these fermented liquors has been replaced by *tari*. Here they are known under the names of *londa*, *henda* and *sonti soru*. The last named was formerly consumed by fishermen on the coast, but the grant of licences for its sale was stopped in 1897-98 because a more wholesome fermented liquor in the shape of toddy was available. Along the Western Ghats in the Bombay Presidency, there is evidence amongst the lower classes of some use of the beer called *boja* prepared from *mandwa*. The Indian Excise Committee (1905-06) however did not find any evidence of its present use there. Our observations in the field show that in certain hilly tracts of the Western Ghats *boja* is still used to

a small extent. Still further south a drink known as *akki bhoja* is largely used, particularly on the Mysore plateau in Milnad. The brewing and consumption of these liquors is subject to little or no control in the non-regulated tracts of the Madras Presidency.

In the following table the vernacular names of these beverages and the localities in which they are used are summarized:—

TABLE I

Vernacular names of beers and other liquors		Localities in which used
1.	<i>Sur, lugri, chang</i> and <i>arrack</i> are distilled from <i>mandwa</i> and rice beer.	Kangra district, Lahoul and Spiti valley in the Punjab and Kashmir.
2.	<i>Rabra, soma, pakhwai, boja, darbakra. Daru</i> (distilled liquor).	Jaunsar taluk of Dehra Dun district in U. P. Bhutya taluq of Kumaon division.
3.	<i>Pachwai, handia, marua, jaur, chanua, niger, kusha, sugda. Rakhsiki</i> (distilled liquor from rice).	In the western districts of Bengal, Bihar and Orissa, Bhutan, Sikkim and eastern parts of Nepal.
4.	<i>Madh, zu, laopani</i> ..	Assam, Nagas, Sadiya frontier tract and Tibeto-Burman tribes.
5.	<i>Boja, londa, sonti soru.</i> ..	Bombay, particularly Maharashtra in Madras.
6.	<i>Akki bhoja</i> ..	Mysore plateau.
7.	<i>Congec</i> ..	Used in Burma by Khyen and Karens.

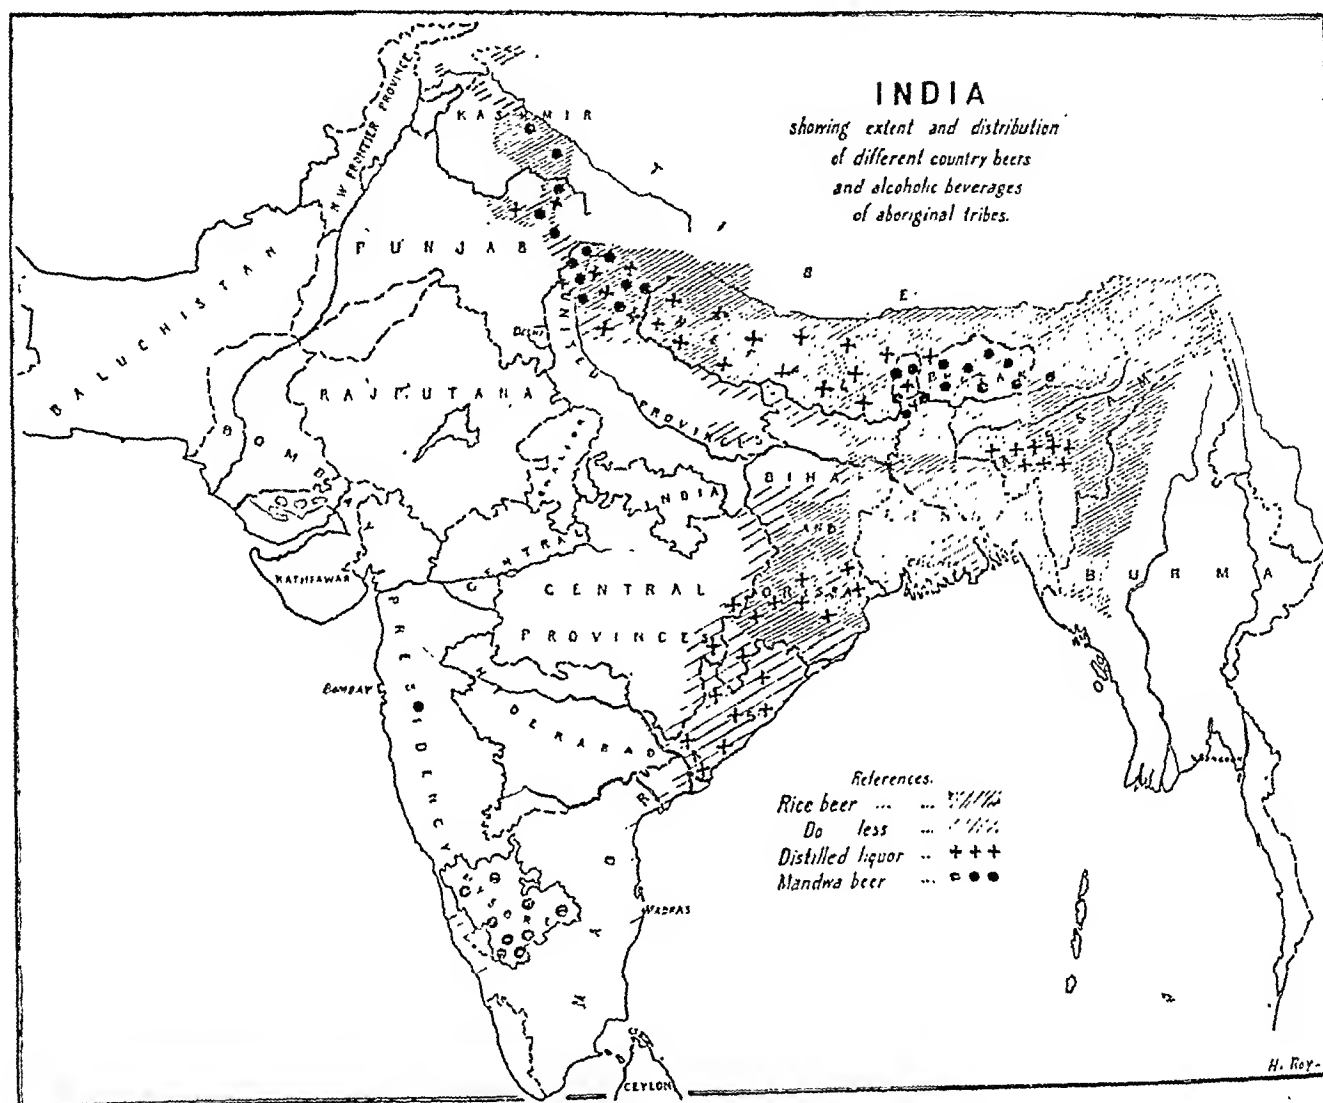

Methods of manufacture.—The two essentials for the manufacture of these beers are a fermenting material and a cereal to ferment:

1. **Fermenting material.**—This is generally supplied in the form of cakes of coarsely-ground corn permeated throughout with dry and empty mycelial filaments of mucus bearing numerous reproductive bodies in the form of chlamydo-spores. Besides, it also contains a certain proportion of the root tissue of a species of *Polygala* which secures in them the presence of a number of reproductive fungal elements capable of retaining their vitality for prolonged periods if they are kept dry. The proportion of *polygala* in the cakes has to be carefully regulated, as an undue proportion may lead to suppression of growth of the fungal elements. On the other hand any defect may fail to suppress the common and useless fructification of the fungus. It is interesting to observe how such difficult formulæ of the proper proportions of the various constituents of these cakes have been worked out by the uncivilized or semi-civilized tribes that resort to the use of these beers. These ferments are manufactured and sold throughout the whole length and breadth of the Himalayas and rarely they are even imported from Tibet, China and Central Asia. In places where the use of these drinks is very prevalent, the ferments are prepared locally under different names by certain tribes, the secret of their composition being carefully guarded. In their preparation a large number of essential elements are mixed

except in a few cases where Rajputs, Goalas, Kurin, Barhi, etc., whose economic condition is very low, have been found to resort to them.

Vizagapatam districts of Madras. In the attached map their distribution all over India is indicated :—

MAP.

In the report of the Indian Excise Committee (1905-06) the distribution of these beers is discussed in a general way and our observations made recently in the field show that the state of affairs has not changed very much since that time. Watt in his *Dictionary of the Economic Products of India* states that these beers are taken in certain tracts throughout India and that there is evidence of their past or present use as far west as Poona, and as far south as Canara and Mysore. They are not used very much, however, in the south where *tari* made from the coconut palm and stronger drinks such as *arrack* are more commonly used. These beers are also drunk throughout Bengal and Bihar with the exception of certain districts where *tari* made from the palmyra and date palms is used. They are also used in the United Provinces along the Himalayas from Azamgarh to Kangra district in the Punjab, and the non-regulated tracts of the Ganjam and

Northern India including the Punjab and the United Provinces.—In the United Provinces and the Punjab there is a small consumption chiefly in the Himalayas and the Tarai. The local names are *darbakra*, *soma*, *rabra* and *boja* in the former and *sur*, *lugri* and *chang* in the latter. The area along which these beverages are used covers the whole length of the Himalayas from Kashmir in the north to Lahoul, Spiti and Kangra. Beverages under the names of *chang* (of Spiti) and *lugri* (of Kulu) are both pernicious and foul-smelling drinks made from fermented rice. Home-brewing is allowed in certain areas under licence.

In Almora, Garhwal, the Jaunsar taluk of Dehra Dun district, Naini Tal and Azamgarh these beers are fairly largely used. In some of these districts home-brewing is allowed and in others their sale is allowed by licensed shops. In parts of Dehra Dun district these beers are drunk largely by certain Hindu races who

or four days when they are taken out, dried and subsequently kept dry, by storage near a fire-place.

The Luchas and Lushis as well as the Nagas make rice beer without adding any special ferment.

2. Cereals used and process of preparation :—

(a) *Pachwai* and *handia*.—These rice beers are the most extensively used of all the country beers. The process of manufacture is simple. Rice is boiled and spread on the clean floor or on a mat, mixed with finely powdered cakes of *bakhar* in proportion of 1 in 100, and left in an earthen vessel in a dark place to allow fermentation to progress. After four to ten days or longer, according to the temperature of the atmosphere and when the fermentation has fully progressed, it is taken out. The mass is then diluted with water which takes up all the alcohol formed and is drunk. The washings are repeated till the mass is bereft of all its alcoholic content and the rice is thrown away or given to pigs.

(b) *Sur* and *lugri* are similar beers prepared from fermented rice and sometimes from other cereals in Kangra district.

(c) *Zu* is a weak country beer which is the national drink of Angamai Nagas. It is prepared by pouring boiling water on rice and leaving the infusion for two or three days in a dark place by which time the fluid becomes fermented and is refreshing and exhilarating to drink. No special ferment to assist fermentation is said to be added in the process of its manufacture, enough ferment being present in the unwashed troughs to start the process.

(d) *Marua* beers (i.e., *chang*, *jaur*, *niger*, *chanua*).—These beers derive their names from a millet called *mandwa* (*Elusine caracana*) which is used in its manufacture. *Mandwa* forms the staple food in most of the hills. The grain is husked, boiled, cooled, and thoroughly mixed with the ferment *murcha*, two to four cakes being added to a maund (80 lbs.) of the boiled grain. The mass is then spread over the floor of a room to a depth of eight to ten inches and kept there from forty-two to forty-eight hours to allow the moulds to develop and spread throughout the mass. The whole mass is then transferred to bamboo baskets which are wrapped in plantain leaves, probably to prevent the introduction of extraneous organisms from the air. The grain is then allowed to remain in these baskets in a dark place for fifteen to twenty days, so that the organisms may produce the desired effect. After this period the grain is ready for use. Some of the prepared grain is placed in a vessel consisting of a bamboo cylinder known as *changa*; hot water is then poured into it and the mixture is left for a time. The liquor is then imbibed through a thin

reed or bamboo pipe. The vessel may be replenished repeatedly with hot water until all virtue is gone out of the grain. If an amount of water equal to that of the grain is added, the wash obtained is called *niger* but if twice the amount of water is added the resultant beverage is called *chanua*. The alcohol content of the liquor when used in this manner is very low (less than 1 per cent by volume), and men, women and children take a delight in sipping it from morning to evening. It is only when the fermented grain is kept steeped in an equal amount of water for twenty-four hours that the percentage of ethyl alcohol rises to six or eight per cent.

(e) *Pakhwai*, *rabra*, *daru*, *lugri*.—These are the common beverages in use in the western Himalayas and the Jaunsar Bewar Pargana of Dehra Dun district. They are prepared in a slightly different manner. A maund of the flour made from one of the common cereals, usually *mandwa*, is taken and made into thick cakes. These are crushed into small pieces and mixed with the ferment *kemki roti* and kept for four to five days in an earthen vessel having a capacity of about four maunds. Usually fermentation starts after this time. Then the vessel is filled with water and again kept in a cool place for about six to eight weeks to complete the fermentation. The resultant fluid is strained and is called *pakhwai*. The semi-solid material left behind is called *rabra*; it contains a certain amount of alcohol and is used as food.

(f) *Daru* or *mandwa* spirit.—This is a drink similar to the country spirit used in the plains. It is one of the choicest drinks of the inhabitants of Jaunsar Bewar and is used on ceremonial occasions such as New Year's day, Dewali, etc., and at marriage or other festivities. The method of preparation is as follows :—Eight seers of *mandwa* flour is baked into a single cake of about eight inches in diameter and one inch in thickness. It is broken into small pieces and mixed with the ferment *kemki roti* and eight seers of water is then added to make it into a homogeneous mass. It is then put into an earthen vessel and stirred twice or thrice daily and after one or two weeks the fermentation sets in. During the winter it may take three to four weeks before it is ready for distillation. The distillation apparatus and the method of its working are described in the diagram on the next page.

Rakhshi.—This is a distilled alcoholic drink used in the eastern portions of the Himalayas, particularly in Nepal and the adjoining areas. It is prepared by distilling the fermented beers used in those parts, e.g., *pachwai* and *marua*. Although distillation is not allowed under the law a large amount of illicit distillation goes on in the hills on the borders of Nepal. Besides this illicit distillation a country spirit called *rakhshi* made from rice is prepared and sold by

with a number of others which are not only unnecessary for fermenting processes, but as will be seen later are sometimes poisonous and extremely dangerous to health. The most important of them are described below :—

(a) *Bakhar*.—This is the most widely-used of all the ferment materials in the manufacture of the rice beers such as *pachwai*. It is stated in the report of the Bengal Excise Commission (1883-84) that 166 different plants and 45 different species have been used in its manufacture. We were able to collect many recipes from the *bakhar* manufacturers of Birbhum and Sonthal Parganas and we have found one hundred roots and 30 stems, leaves and flowers mentioned, which were said to be used in its manufacture. The list included poisons like *dhatura*, *aconite* and *nux vomica*. The commonest ingredient was a plant called 'Rannu' in Sonthali. Another common ingredient of the cakes is a plant known as 'Sarum Lutui' (*Clerodendron serratum*) which was especially used to enhance the intoxicating properties of the beer. In the northern Himalayas a grass, *Hardeum vulgare* Linn., is employed in the manufacture of these ferments. According to Ray (1906) the plants used in the preparation of *bakhar* may be divided broadly into four groups with regard to their known general properties :—

(1) Some possess medicinal properties, e.g., *Tribulus terrestris* (gokhur); *Desmodium gangeticum* (sálpán); *Uraria lagopodioides* (chakulia); *Splavum jacquini* (kantakari); *Hemidesmus indicus* (anantamul); *Asparagus racemosus* (satamuli), etc.

(2) Some contain bitter principles, e.g., *Andrographis paniculata* (kalmegh); *Oldenlandia herbacea* (khetpapra); *Azadirachta indica* (nim); *Justica adhatoda* (basak), etc.

(3) Some contain tannin, e.g., *Terminalia chebula* (haritaki); *Terminalia tomentosa* (piásil); *Cassia fistula* (sondal); *Diospyros tomentosa* (kendu), etc.

(4) Some contain narcotic principles, e.g., *Datura* (dhutura); *Plumbago zeylanica* (chita); *Strychnos nux vomica* (kuehila); *Cannabis sativa* (siddhi); *Aconitum palmatum* (bhikhma).

The first investigation of a scientific nature regarding *bakhar* was made by Ray (1906). He thinks that the saccharification of rice as well as the subsequent alcoholic fermentation are due to the activity of a micro-organism present in *bakhar* to which he gives the name *Mucor torula*. The next investigation on *bakhar* was made by Hutchinson and Ram Ayyar (1915). Contrary to the view expressed by Ray, they concluded that the changes were brought about by two distinct classes of micro-organism, namely, mucors and yeasts. Interesting observations were also recorded by these workers with regard to the relative physiological activities of the different micro-organisms

found in *bakhar*. A fungus named *Aspergillus oryzae* isolated from the Japanese koji, a substance analogous to the Indian *bakhar*, was found to possess the greatest saccharifying activity. Several specimens of *bakhar* were prepared in the Pusa laboratory by mixing pure cultures of *Aspergillus oryzae* and other mucors with yeasts and the comparative strengths of the alcohol produced by them from rice were recorded. Attempts were made by these workers to produce the crude *bakhar* from cultures of mucors and yeasts. *Aspergillus oryzae* a fungus isolated from the Japanese koji and several varieties of yeasts were utilized in the preparation of different types of *bakhar*. The results however were not satisfactory. The maximum strength of alcohol obtained by the action of these *bakhars* on rice was 33.7 per cent (59 per cent proof) against the maximum of 18.3 per cent (32 per cent proof) by volume, recorded with ordinary crude *bakhar*, thus showing that the product obtained experimentally in the laboratory was not identical with the crude product. Although the peculiar apple-like odour associated with the growth of *Aspergillus oryzae* was present, the taste of the *pachwai* prepared from the laboratory *bakhar* did not come up to the standard and liking of the consumers generally. *Mucor amylomyces* used in European distilleries is very similar to the organism found in *bakhar* and other fermenting substances used in the preparation of these beverages.

(b) *Kemki roti*.—This is the ferment used in Jaunsar and in the western Himalayas. Powdered and dried roots of several hill plants are mixed with four times their weight of *mandua* flour and made into a cake 2½ inches in thickness and 10 inches in diameter. The vernacular names of the plants used are *chhamur*, *artoo*, *mukrand pahar*, *baru*, *charwa* or *chharanta*, *doodth pal* and *sonti*. The mixture is then covered with straw and placed in a dark room for eight days or so, depending on the time of the year; after this it is taken out and dried in the open air for four days. The black fungal growth which occurs on its surface is wiped off, and it is then ready for use.

(c) *Murcha cakes*.—These are commonly employed in the eastern Himalayas, Assam and Bhutan hilly tracts. The outer skin of the roots of certain wild plants known as 'bhimsen-pati' (*Buddleia asiatica*), 'lour' and 'wadding-hang-ma' (*Polygala arillata* Ham.) are dried, powdered and mixed with other ingredients in the following proportions:—Dried roots 6 ounces, dried ginger 1 ounce, 6 chillies and rice flour 12 pounds. Sometimes one or two seeds of *Strychnos nux vomica* are added and the mass is then kneaded into a dough with water. Small round cakes are prepared and dusted over with an old powdered cake from a previously manufactured batch. They are then covered with fern leaves and kept in a dark room for three

and his results are given in the following table :—

Average strength of country beers (1905-06)

Province	Number of analyses done	Percentage of absolute alcohol by volume
Bengal	.. 8	6.4
Eastern Bengal	.. 4	6.9
United Provinces	.. 1	13.6
Punjab	.. 3	6.3
Burma	.. 7	9.9
Mysore	.. 1	4.1

In the following table the results of the analyses of similar specimens examined at the Municipal Health Laboratory, Darjeeling, during recent years are given :

TABLE II

Showing the results of the analyses of country beers done in the Municipal Health Laboratory, Darjeeling

No.	Specimen	Specific gravity	Percentage of ethyl alcohol by weight	Percentage of alcohol by volume
1	Undiluted pachwai, chanua.	0.9870	13.1	22.9
2	Undiluted pachwai, niger.	0.9981	10.68	18.7
3	Undiluted chanua.	0.9894	2.65	4.6
4	Diluted pachwai, niger.	0.9915	10.85	19.0
5	Do.	0.9803	4.33	7.6
6	Do.	0.9864	8.03	14.1
7	Chanua	0.9888	6.71	14.6
8	Do.	0.9968	1.8	4.0
9	Do.	0.9933	..	8.7
10	Do.	0.9945	..	6.8
11	Do.	0.9884	..	12.9
12	Do.	0.9915	..	10.8
13	Do.	0.9895	7.5	13.5
14	Do.	0.9903	7.09	12.4
15	Do.	0.9888	..	14.6
16	Do.	0.9932	..	8.29
17	Niger	0.9865	8.29	18.03
18	Do.	0.9944	3.1	7.0
19	Do.	0.9894	..	3.7
20	Do.	0.9930	..	8.75
21	Do.	0.9896	..	14.5
22	Do.	0.9894	..	13.7
23	Do.	0.9932	5.0	8.7
24	Do.	0.9822	14.18	24.8
25	Do.	0.9899	..	12.95
26	Do.	0.9876	..	16.4

A perusal of these results will show the large variations in the alcoholic contents of these beers. In three the strength of alcohol is very small, i.e., below 5 per cent, in seven it is between 5 to 10 per cent, in ten it is between 10 and 15 per cent, in four it is between 15 and 20 per cent, and in two it is between 20 and

25 per cent. It will be observed therefore that considerable quantities of alcohol could be consumed if these liquors were made stronger. Fortunately, however, in the majority of specimens the strength of alcohol is less than 15 per cent by volume, and this decreases the chances of drunkenness and noxious effects from this source.

Etiological factors.—These can be grouped under the following heads :

(1) Environmental and climatic factors. (2) Belief in medicinal value. (3) As foods and euphorics. (4) Religious, social and ethnological customs and beliefs.

An analysis of a large number of habitués examined by us shows that, with regard to the cause of their addiction, they can be roughly divided into two groups.

(a) Those who start early in life, i.e., before 30 years of age. Eighty per cent of the habitués started the use of these liquors before 30 years of age and in the majority of instances because of the prevalent belief regarding their tonic, exhilarating and nutritive properties. Association with and suggestion of their elders played an important part in their starting the use of these liquors.

(b) Those who start later in life, i.e., after 30 years of age. They comprise a small group some of whom took to these liquors because of their supposed beneficial effects in overcoming worry and fatigue, generally the result of hard work. Others took to them to promote appetite and digestion, and still others as a protective against the trying cold weather of the hills.

(1) *Environment and climate.*—In our series as many as 60 per cent admitted that they started these beverages from no other reason than the example of or association with their parents, relatives or friends. The parents sometimes, on account of the belief regarding their beneficial effects on health, give small quantities of the diluted liquors to their children. In cold and damp climates, particularly in the hills, large numbers of people start using these liquors as a protective against chest diseases, cough, etc., and finally they become habituated to them. The use of fermented liquors for similar reasons also prevails in areas of heavy rainfall, e.g., in the mountainous and sub-mountainous tracts of the Himalayas, Chota Nagpur hills and along the Western Ghats.

(2) *Belief in their medicinal value.*—When a relative or friend is feeling out of sorts or scedy usually a man habituated to these liquors suggests a dose as a curative. There is a strong belief amongst the inhabitants of these regions that these beverages are a necessity for everybody, as they keep out damp and cold and are a prophylactic against malaria.

(3) *As foods and general euphorics.*—Many of these beverages have a considerable food value. During the process of fermentation many indigestible carbohydrates are converted

contractors licensed by Government. This liquor is largely used by the Nepalese section of the population of the Darjeeling district and the higher-class Bhutyas residing there.

Diagram showing the apparatus and method of manufacturing rakshi (rice spirit)

Diagram showing the apparatus and method of manufacturing mandwa spirit

(h) *Chang*.—This liquor is used in distilled or undistilled form in the hills towards Spiti, Lahoul and Kashmir.

Cereals used and composition of beers.—The cereals most commonly employed are rice and mandwa. The husked grains have the following composition :—

	Rice per cent	Mandwa per cent
Water	.. 12.8	13.2
Albuminoids	.. 7.3	7.3
Starch	.. 78.3	73.2
Oil	.. 0.6	1.5
Fibre	.. 0.4	2.5
Ash	.. 0.6	2.6

During the process of manufacture, starch is converted into sugar which later becomes converted into alcohol. These changes are brought about through the agency of various moulds and yeasts present in the fermentation cakes. Moulds such as *Rhizopus cambodja*, *Dematium* and *Penicillium* and one kind of yeast gain entrance into the fermentation cakes either from the skin and roots of the various plants used, or from the air or the green leaves used to cover the cakes during the process of their manufacture. The enzyme amylase secreted by these moulds changes the starchy matter into maltose which is then converted into glucose and ethyl alcohol by the activity of the maltose and zymase of yeast. Fermentation enzymes are also secreted by the moulds to a small extent.

Besides diluted ethyl alcohol, these liquors contain other starchy derivatives such as dextrine, malto-dextrine, maltose, etc., which have not been fermented. The food value of these liquors is therefore substantial. The nature of the by-products depends upon the character of the grain and the fermenting material used. In most of the fermented liquors glycerol is formed from decomposition of sugars by yeast; fusel oil is formed from amino-acids by the decomposition of proteins present in the grain; succinic, formic and acetic acids are produced and some other acids may be formed as a result of bacterial contamination. Besides these many esters, and aldehyde and ketone bodies, which are responsible for the smell and taste of these fluids, are formed.

Alcoholic strength.—The fermented mass has a semi-solid consistency and contains fair quantities of alcohol. The strength of the ultimate product depends partly upon the nature of the grain employed but much more upon the amount of water added to dilute it. The amount of water added varies in different places, amongst different tribes, and according to the occasion on which the liquors are used; for instance the liquor drunk at festivals and marriage ceremonies is much stronger than that used for daily consumption.

Bedford, at the instance of the Indian Excise Committee (1905-06), examined the alcoholic contents of a number of samples of rice beers collected in various parts of India

remainder six bottles and more. The number of those who drink excessive quantities and reach the stage of intoxication is small, certainly not more than 5 to 10 per cent even on Saturdays and Sundays, when the consumption is the highest. The plea used by advocates of these beers, namely that the quantity of the daily dose is moderate, is well borne out by our observations.

Sex incidence.—Unlike narcotic drugs in this country, these beverages are taken by members of both sexes alike. Forty per cent of the habitués in our series were females and among them there were many children of both sexes. The female habitués mostly take these liquors in moderate quantities as a mild euphoric and as food after a hard day's work or to keep off the cold. Women usually drink in their homes and we have very rarely seen them drinking in the licensed shops.

EFFECTS PRODUCED.

It may be emphasized here that the aboriginal races only drink fermented liquors and that the distilled liquors we have mentioned, e.g., *chang* from distillation of *mandwa* beer and *rakhshi* from rice beer, appear to be entirely an innovation brought by the Aryan races. In the following pages the effects of these beers and not of the distilled liquors are discussed.

There is a great deal of difference of opinion as to whether these liquors are wholesome or harmful stimulants. The effects produced by them are somewhat similar to those of ordinary malt beer. The immediate effects in habitual consumers are refreshing and stimulating. They alleviate fatigue and give rise to a sense of pleasure and general comfort (euphoria), accompanied by a feeling of vigour, and capacity for work. According to the habitués, these beers remove restlessness, induce forgetfulness and soothe the nerves. The drinkers are at first inclined to be silent but they soon begin to talk, become happy, courageous and even hilarious. They become sociable, the eyes brighten up and the usual depressing effects of alcohol on the higher centres become apparent. With larger doses the symptoms observed are similar to those met with after strong alcoholic drinks.

As regards the production of harmful effects our experience in the field is very much the same as that of the witnesses who appeared before the Indian Excise Committee. These liquors are not always innocuous and sustaining as is claimed by some people, and they undoubtedly lead to much waste of food material. Cases of excessive drinking have been reported and even deaths have been recorded in different areas after heavy indulgence. We have carefully studied the question of the fatal effects produced by the use of these liquors and have come to the conclusion that, even if inordinately large quantities are consumed, it would be difficult to take enough alcohol to produce stupor, coma

and death from drinking the ordinary rice or *mandwa* beers. Most of the cases of poisoning are undoubtedly due to drugging of these beverages. The allegation of drugging has been made in most of the provinces and, although in the case of spirits and *tari* evidence has been wanting, it has been obtained with regard to the country beers. In quite a number of the fatal cases, *dhatura*, *nux vomica* and *aconite* have been detected in sufficient amounts to produce death by over-indulgence in the beer containing them. All these poisonous substances have actually been detected in the fermenting cakes of *bakhar*. These drugs are surreptitiously added with the idea of giving the liquors a bitter taste and also of increasing their intoxicating effects.

Nutritive and digestive value of beers.—Beers generally are regarded as stimulating, refreshing and thirst-quenching beverages but doubts have been expressed regarding their food value. According to Bedford some of them contain 1.35 grammes of sugar and 0.65 gm. albuminoids per 100 c.cm. and some even contain larger quantities. There is no doubt therefore regarding their food value. In fact they have the combined value of food and stimulant. The quantities of carbon dioxide and other substances present may even promote digestion by stimulating various digestive juices and thus they may act as adjuncts in facilitating the digestion of other foods. They also supply quantities of salts of potassium and sodium, calcium phosphate, etc., which are among the more important of minerals required for the repair of the tissues after hard physical exertion. It is well known that plants of all kinds, including lower forms of vegetable growths, contain water-soluble substances which promote growth and nutrition. Brewer's yeast is a recognized source of vitamin. The crude beers which contain both these substances (moulds and yeasts) should therefore form very rich sources of growth-forming water-soluble vitamins belonging to the groups B₁ and B₂ and probably also vitamin C.

Most of these races are very poor and cannot always secure for themselves a varied diet containing all the principles required for proper nutrition. Our enquiries have convinced us that the majority of these tribes are subsisting on a poor, restricted and sometimes unbalanced diet of a monotonous character. It is remarkable however that these primitive people are peculiarly free from any of the deficiency diseases which have wrought havoc in several parts of the world from time to time. The beers have been shown to be rich sources of vitamins and it is not unlikely that the supply of vitamins through the agency of these beers is responsible for the lack of deficiency diseases in these communities. Yeasts also contain hæmatopoietic principles and have been used successfully in the treatment of anæmia.

into more readily assimilable sugars. The nutritive value of rice beers, such as *pachwai*, *zu*, etc., is undoubtedly substantial. The Nagas never drink milk or use milk as food. They always drink the rice beer, *zu*, prepared in their own homes. In the mountainous regions of India where economic conditions are poor and the natural craving for a stimulant is greater on account of climatic conditions, the use of a variety of beers and spirits, offered at prices commensurate with the means of the people, has come into vogue. These mild drinks are to the poor what the different varieties of expensive alcoholic liquors are to the well-to-do.

The habit of taking these beverages begins at a very early age. In some parts the children start small doses of the beers but this is an uncommon practice. Mostly, people resort to these drinks in order to tide over the feeling of exhaustion after a day's hard labour in the fields, in the tea gardens or during the trying winter season. *Pachwai* is used by practically all the male and female workers in the coal-mining districts of Bengal and Bihar, and they indulge in it after finishing their work which involves a considerable amount of physical strain. The doses taken are often moderate, just sufficient to relieve the feeling of fatigue and ensure sound sleep. We have been informed by men working in this area that their work is so hard, uninteresting and monotonous that it would be impossible for them to get through it every day if they did not take this beverage. In fact many become so used to it that they are unable to work if they do not get it and similarly the prospect of getting it is often an incentive for work.

(4) *Social, religious and ethnological factors.*—The use of *pachwai* is considered necessary at religious and social festivals by Sonthals, Garrows, Koch, Dhangars, Mandais, Tipperas and other similar aboriginal tribes. The Sonthals, especially the women, object to the use of *pachwai* that is bought from a shop.

There is a general belief amongst the hill tribes that fermented liquors are less injurious than distilled spirits. The use of these fermented liquors is not only permitted but sometimes it is encouraged by custom. On the occasions of religious worship amongst many of the backward races inhabiting the Western Ghats and in the hilly tracts between Chota Nagpur and Godavari, the use of these liquors is considered necessary. Men, women and children all indulge in these drinks, there being no restriction as to caste or creed. Among the Sonthals and Bhumij tribes of Chota Nagpur these liquors are considered to be indispensable at funerals, marriages and other ceremonial occasions. The Mohammedans are forbidden by their religion to take alcohol and that is the reason why in the western Himalayas, where the population is predominantly Mohammedan, these liquors are not much used.

Ethnological factors.—It has been said that the Aryans and the white races who introduced the use of alcohol from their original home in central Asia have grown more temperate, while the races of aboriginal stock all over the world, who have been less exposed to the use of alcohol, are more prone to get addicted to its use and to abuse it. Our experience among the races using these beers is that if they can get stronger distilled liquors they will always drink to excess, and drunkenness from this cause is common where economic conditions allow primitive peoples to buy stronger drink. Fortunately this is not very often the case and their means do not usually allow them to go beyond the cheap beers.

Mode of consumption.—In their own homes the amount consumed as a rule is not large but in the licensed shops these people are liable to take larger quantities. The usual dose varies between one to six bottles ($\frac{1}{2}$ pint capacity) daily for an adult man and usually four to six bottles are sufficient to produce exhilaration and mild intoxication. We have however seen persons who can take the weaker beverages the whole day long without any apparent signs of intoxication. The habitués usually assemble in the evening in one of the licensed shops where they sit and drink in company. In the mining areas of Bengal and Bihar there are a large number of shops and any afternoon, particularly on Saturdays and Sundays, one can go and watch thousands of these workers indulging in their favourite drink *pachwai*. *Rabra* and *pakhwai* are frequently used in Jaunsar during the working months from April to October. The semi-solid material serves as a food and is also slightly stimulating like other country beers. It is believed to allay the feeling of hunger and it enables men to carry on their work for long periods during the harvesting season. *Pakhwai* and *rabra* are taken all the year round but *mandwa* wine, which is stronger, is taken only on marriage or other festive occasions.

The following data have been collected after a study of a large number of habitués :—

Age of beginning.—In the majority of cases we have examined, the use of these beverages is generally started in childhood. In our series all except a few persons started it before attaining the age of adolescence.

Present age of consumers.—An analysis of the cases collected by us shows that as many as 70 to 75 per cent of the drinkers are between the ages of twenty and forty years. The highest number of habitués falls between thirty and forty years of age, next in order being those between twenty and thirty years. The number of those indulging in beer after fifty is comparatively small.

Dosage.—More than 50 per cent of our series took up to two bottles ($\frac{1}{2}$ pint capacity) a day, 30 per cent two to four bottles daily and the

persons among the sections of the population who use beer in this way must be very small indeed.

The witnesses who appeared before the Indian Excise Committee (1905-06) expressed the opinion that even excessive use of these beers is less harmful than that of strong spirituous drinks so long as the liquor drunk is not contaminated with deleterious substances. Bedford carefully studied the question of the alcoholic contents and by-products contained in these beers. In point of by-products he found that these beers undoubtedly contain a high percentage of acidity and a much higher proportion of fusel oil. The quantities of furfural present however was less than in country spirits. The beer drinkers therefore consumed comparatively small quantities of alcohol but very much larger quantities of the by-products (except furfural). The general consensus of opinion was, and this is borne out by our own recent observations, that fermented liquors are very much less harmful in their effects than the spirits containing a high percentage of ethyl alcohol.

A large amount of experimental work was carried out by Bedford (1905-06) and recently by Chopra (1927) on both animals and men regarding the toxic effects of alcohol itself and the various by-products of fermentation. The conclusions arrived at by these observers are in accord with each other. These are (a) that alcohol alone is at least as deleterious as alcohol plus by-products, (b) that whilst the by-products are undoubtedly noxious in amounts far exceeding those found in potable liquors, in the relatively small quantities found even in the worst samples of the liquors analysed, their action would appear to be unimportant and negligible and (c) that spirit drinking is more noxious than the drinking of fermented liquors because the toxic amount of alcohol absorbed is more quickly reached and more easily exceeded. Alcohol and not the by-products is chiefly responsible for all the toxic effects produced by potable spirits. Any evil effects observed were more attributable to the excessive quantity of alcohol consumed than to any specially deleterious by-products.

From the experimental data obtained and from our observations in different areas, we are in a position to conclude that these fermented liquors do not produce any special harm when the concentration of alcohol is low and the consumption is not excessive. The age-long experience of the hill tribes in India points to the fact that fermented beers are on the whole less harmful than distilled spirits. The by-products are not harmful in the concentrations in which they are present in these liquors unless very large quantities are taken for prolonged periods. During the course of our inquiry we have not found any greater preponderance of cirrhosis of

the liver or any of the other conditions usually attributed to the excessive use of alcohol among these races than are ordinarily met with in races who do not use these liquors.

From our own observations in different parts of the country where these liquors are used we have come to the conclusion that the use of these fermented liquors is less harmful, and that the country spirits and other distilled liquors are more injurious, because with these strong drinks the toxic limit of alcohol to the human system is more quickly reached and is more easily exceeded.

Any attempt at suppression of these liquors will probably lead to more extended use of distilled spirits or harmful drugs among these races. Home-brewing, in the areas in which it is allowed, appears not to be causing drunkenness and deleterious effects generally. A quite different factor responsible for ill-health in the consumers is the insanitary conditions under which these beers are manufactured. The utensils may not be properly cleansed and impure water be used in the preparation, and to these facts might be attributed the occurrence of diseases such as dysentery, diarrhoea, cholera, tuberculosis, typhoid, etc. Finally it must be mentioned that beers after storage may taste stale and sour on account of bacterial contamination when by-products, such as acetic acid and lactic acid, are formed. The harmful effects of these drinks appear to be due more to the unsatisfactory methods of preparation and storage than to the actual harmful effect of alcohol proper.

Drunkenness.—This is largely dependent on the locality. Some of the races drink these liquors to intoxication if opportunities present themselves. The hill tribes of Bengal will take large quantities if they can get the products ready-made in shops, but on account of the paucity of the supply of rice they are not inclined to manufacture beers in their own homes. Drunkenness with *pachwai*, which is considered to be a comparatively mild and wholesome drink, is not an uncommon occurrence in the mining areas in Bengal and Bihar. The evidence in favour of *pachwai* being taken mostly for its nutritive effects is also not so strong as in the case of such beers as *zu* and *laopani*, as the rice in the former becomes unpalatable and bitter after fermentation, and is not consumed but is thrown away.

In Assam among the hill tribes the beers ordinarily consumed are weaker and the manner of their consumption is different, the liquor being taken in the form of a thick gruel and the rice eaten with it. It is a part of the dietary of the inhabitants of the whole range of hills right up to Tibet and Burma. These tribes, who have a fine physique and are hardy, use as much as 25 per cent of their rice crop for this purpose. This in itself is a proof that this beer cannot be very harmful. Drunkenness of a convivial kind however does occur among these tribes and many individuals become incapacitated for days together after these bouts. Among tea-garden coolies things are much worse and there is considerable drunkenness from this cause. The coolies get so habituated to the use of these beers that they will starve themselves in order to get rice for brewing *laopani* or *zu*. On these grounds some of the local officials have urged the total suppression of these liquors. On the other hand, others are of the opinion that any attempt to restrict their production would do more harm than good and would encourage drinking of stronger liquors. From our own observations on these drinks in different places we are inclined to agree with the latter view.

In the United Provinces all the evidence goes to show that excessive use of beers and drunkenness is confined chiefly to festive occasions. In Jaunsar taluk *pakhwai* and *rabra* are mainly used on such occasions as New Year's day, Dewali and certain other festivals. In the Punjab evidence of drunkenness and even of debauchery was produced before the Excise Committee, but as a rule *lugri* drinking is only conducive to merry-making of a harmless type. In southern India these beers are used to a much smaller extent, there being only one or two small areas where they are still consumed. The use of beers to the extent of producing uncontrollable intoxication is rare. Repeated doses of these liquors, particularly when undiluted, may produce a state of intoxication similar to

that commonly produced by stronger forms of alcoholic drink. The accompanying regardlessness of danger and feeling of bravery induced in such cases is partly the result of the temperament of these more-or-less primitive races, but it is also in many cases due to a state of mental confusion induced by poisons such as *dhatūra*, *aconite* and *nux vomica* that have been added to these beers.

In addition to such instances of intoxication where there is a distinct motive, there are some cases that correspond to those of alcoholics in western countries. There are, however, few instances of the type of drinker amongst these country beer-consumers who intoxicates himself with these liquors for the sake of being intoxicated. From our observations we are justified in concluding that gross instances of producing motiveless drunkenness from country beers, corresponding to the excessive drinkers of alcohol in the western countries, are very rare.

Withdrawal symptoms of a mild type rarely occur even among those who habitually indulge in excessive doses of these liquors, they occur more commonly among those who consume distilled liquors in addition. Such persons state that when the drink is not obtained they feel a strong desire for it and that they become very depressed. In some, a feeling of chilliness and disinclination for work accompanied by loss of appetite is observed. In such cases a glass or two of these drinks will restore them to their normal state of health and mind.

Deleterious effects of beers.—During the last two years we have visited most of the areas where these liquors are used and have been able to study a large number of their users. From the data collected it is clear that the habitués may be grouped into two main classes with regard to the effects produced by these drinks.

The first are the tribes inhabiting the Assam hills and hill tracts right down to Burma, who use beer as an article of dietary or as a bland and mildly-stimulating drink. The Nagas drink these beers in lieu of water, and these hill tribes are noted for their fine physique in spite of using beer on a most extensive scale. We have not been able to detect any mental and physical deterioration in habitués of this class. All these persons are useful members of society and carry out their vocations in life which involve very hard physical work.

To the second group belong those who use beer primarily for the intoxicating effects produced by alcohol. To this category belong most of the races living in the plains and low-lying hills.

Both classes undoubtedly contain a certain number of psycho-neurotic individuals who are unable to bear the strain and stress of life and resort to these liquors, but the number of these

involvement of the musculospiral nerve. He can carry heavy office chairs and do the work that might be expected of an ordinary coolie with ease, *see figure 3*, and with his clothes on it is difficult to suspect that the arm has been injured in the manner described.

The individual is above the average in muscular development and gives the impression of being a remarkably tough fellow of unusual vitality.

This is the first case of this nature that I have seen, but recovery of function to a remarkable degree after failure of union would appear

Fig. 3

to be a special feature of injuries in this region, as a remarkably similar case is described by Sir John Coolie in his book, *Fraud in Medico-Legal Practice*, page 11. Sir John Collie describes his case in detail to illustrate the need for thorough examination in medico-legal work. His patient, a sailor, had done strenuous able-bodied work for 18 years and was at great pains to conceal his disability. He boasted, after exposure, that he had deceived between

20 and 30 doctors to whom he had been sent for physical fitness examinations.

The individual whose condition is described in this note had been sent to me for the usual periodical medical examination for physical fitness and visual acuity prescribed for railway employees. He was, like the sailor, very keen to prove that he was fit in every way.

As a railway surgeon I am not infrequently concerned with compensation cases under the Workman's Compensation Act, and it is of some interest to speculate on the possible outcome of this man's injuries had they occurred to-day under the present rules. The assessment of his present disability would certainly present difficulties.

Pseudarthrosis after non-union of fracture does not appear to be as common in the upper arm as in the forearm, where, if both bones are fractured, non-union with a false joint is more likely to occur than in any other part of the body. As a rule the only satisfactory treatment is bone grafting. This man was offered an operation of this type but refused. In his state of life I think he was wise.

I have to thank Dr. R. V. Clayton, M.B., D.P.H., D.M.R.E., Principal Medical and Health Officer, G. I. P. Railway, for permission to publish this case, and my assistant Dr. M. Roskino for the illustrations and radiogram.

VOLVULUS OF THE SIGMOID

By P. BANERJEE, F.R.F.P.S., F.A.C.S., F.R.S.E.

MAJOR, I.M.S.

Civil Surgeon, Bakarganj

VOLVULUS is possible in any portion of the intestinal tract from the stomach to the sigmoid colon. Thus volvulus of the stomach, due to gastropexia, an hour-glass contraction or certain kinds of injury, although extremely rare, is known. Volvulus of Meckel's diverticulum when it is persistent is recorded. Similarly volvulus of the small intestines, the ileo-caecal junction or even of the caecum occurs but very rarely. The commonest volvulus is that of the sigmoid colon. This portion of the colon, on account of its peculiar anatomical structure in having a very narrow-based but long mesentery which spreads out in a fan-shaped manner, is easily susceptible to twisting. The length of the loop suspended from this narrow mesentery varies from nine to about twenty inches and it is extremely mobile. The two ends of the loop are very closely approximated owing to the nature of the mesentery. The narrower the base of attachment which may be a normal condition or may be caused by inflammatory adhesions, as a result of infected lymphatic glands, or chronic inflammatory and ulcerative conditions of the loop itself, the greater is the tendency of the bowel to be twisted. The lengthening of the bowel on

PSEUDARTHROSIS OF HUMERUS

By H. R. RISHWORTH, F.R.C.S. (Eng.)

District Medical Officer, G. I. P. Ry., Hony. Consulting Surgeon, St. George's Hospital, Bombay

THE following case appears worthy of record and may be of interest to practitioners who are concerned with cases of injuries 'arising out of and in the course of employment'. It illustrates the extraordinary powers of recuperation and adaptation possible in the human subject.

M. S., employed as a gateman in the railway service, aged 45 years, was injured on duty while working as a porter about 15 years ago. The left humerus sustained an open comminuted fracture about its middle, and the upper end of the left femur in the region of the great trochanter and the neck was comminuted without any external wound. A radiogram of the upper end of the left femur showed an extensive healed fracture. He was treated in the railway hospital and was able to walk after about five

from abnormal stresses in the joints of the left lower limb. The left arm has a gap in the bone about the middle of the shaft, the soft tissues between the ends being about three inches in circumference. The radiogram, figure 1, shows

Fig. 1

months. Several pieces of bone were removed from the wound in the upper arm before healing was complete. He was provided with a job as a gateman and has performed this work satisfactorily ever since. He walks with only a slightly perceptible limp although the left limb is $1\frac{1}{2}$ inches shorter than the right. There is no evidence of a compensatory scoliosis and the radiogram does not reveal any osteoarthritis

Fig. 2

an irregular rounding of the bone ends with complete closure of the medullary cavity. Four small shadows of isolated fragments of bone can be seen between the broken ends. Great mobility exists at this pseudarthrosis. Figure 2 illustrates the extraordinary range of movement possible in the arm. To attain the posture figured some assistance from the right hand was used to swing the injured arm behind and above the head. The arm of course cannot be extended at full length but considerable muscular power can be exerted when the arm is used with the false joint flexed. The muscles of the arm are well developed and there is no wasting, as can be seen from the illustration. There is no

increased, and thus the normal pulse and respiration ratio is disturbed.

Except in the very early case, when an attempt may be made to relieve the condition by passing a flatus tube once, no delay should be made in opening the abdomen. When operation is performed early, the volvulus is easily recognized directly the abdomen is opened. In late cases, however, along with the twisted portion of the colon other distended coils of large bowel are seen and it is difficult to make out which is the twisted loop. I have, however, found that the twisted loop of sigmoid presents a different colour from that of the others. It will be found to have a greyish-blue colour in contrast to the rest of the dilated large bowel, which has a reddish-purple colour. The difference in colour is certainly due to the practically complete obstruction of circulation in the twisted portion of the bowel. It is not seen in cases where there is only half a twist, as in these the sigmoid with the rest of the large bowel has the same colour. Where gangrene has already set in and the patient's condition is very low, no attempt should be made to resect the bowel, but if possible the twist should be undone and the gangrenous loop brought outside the abdomen and excluded, after dividing it above and below, from the rest of the sound bowel.

The separated gangrenous loop and the openings above and below it should then be fitted with Paul's tubes for lavage and drainage. Immediate resection and anastomosis in a patient suffering from a high degree of toxæmia and shock very often prove fatal in India even when the operation is performed quickly. But it may be done later when the condition of the patient has improved. When gangrene has been extensive, necessitating removal of a very long piece of bowel, even end to end anastomosis may not be possible. The only course then left is to create an artificial anus as in colostomy with the lower end of the descending colon and close the upper end of the rectum.

If only one or two small patches of gangrene are seen these may be excised and the openings closed by purse-string sutures covered by Lembert stitches.

In certain cases, one may find the loop so fixed by adhesions at the point of the twist that it cannot be untwisted. Of course the only immediate surgical measure then possible is to drain the upper and lower limbs of the loop. I have myself not seen such a condition.

In the generality of cases, I suggest the following operation :—

The abdomen should be opened on the left side by a left paramedian incision extending from three to four inches above the umbilicus to an inch or an inch and a half above the pubic symphysis. The abdomen is entered from the inner side of the rectus muscle. In very early cases the volvulus will be found occupying

partly the pelvis and partly the lower abdomen, and the loop will be easily recognized from the rest of the distended colon by its peculiar colour which I have described above. It should be carefully taken out and untwisted. So long as the distended loop is not extracted from the abdominal cavity, it is difficult to determine the direction of the volvulus. I consider it therefore necessary for it to be brought out of the abdominal cavity. As soon as it is untwisted a rectal tube should be passed to relieve the dilatation by letting out any gas and as much of the fluid faeces as possible. More than one tube should be kept at hand as they get rapidly choked with faeces.

In a case where the dilatation is extreme and the loop occupies the whole of the abdominal cavity reaching up to the under surface of the diaphragm, it is inadvisable to attempt to drag it out of the abdomen even through a large opening. In the attempt the bowel may easily be ruptured. In such circumstances, the part of the distended bowel, which presents itself in the abdominal opening, should be punctured to relieve the distension, every care being taken to prevent contamination of the peritoneal cavity. This opening should be closed with purse-string and Lembert sutures as soon as the distension is relieved. It will be easy now to bring out the volvulus and untwist it.

It is a well-known fact that recurrence of volvulus is frequent because the pathological condition which causes it cannot be remedied. Plication of the mesentery to shorten it, fixation of the bowel to the lateral parietal peritoneum, and lateral anastomosis between the two limbs of the sigmoid loop have all failed to prevent recurrence. Resection of the loop and anastomosis have been recommended. This is, however, a very severe operation for a patient in a state of shock and toxæmia. I think that a lateral anastomosis between the two limbs of the loop, followed by fixation of the upper limb to the parietal peritoneum laterally, will be found effective and is certainly less severe than resection and anastomosis. The lateral anastomosis must be large, at least four to five inches in length. Thus the canal will be short-circuited for the passage of faeces, and the loop will practically cease to exist. It will form a single tube fixed to the abdominal wall.

Where the sigmoid loop is very long it may be lifted out of the pelvis, its upper limb laid parallel to the descending colon and fixed to it by lateral anastomosis, the lower limb being fixed to the iliac parietal peritoneum.

The limb to be fixed should be stretched and laid parallel to the parietal peritoneum on the lateral abdominal wall nearest to it and then stitched to it by a continuous catgut suture passed through its anterior longitudinal band.

The operation should be performed under local infiltration anaesthesia preceded by a

(Continued at foot of next page)

account of its being constantly loaded from chronic constipation is yet another factor which predisposes to volvulus. All these factors lead to thickening and fixation of the narrow base of the mesentery and thus the parietal attachment forms an axis round which the bowel may readily get twisted.

The exciting factor may be sudden and excessive peristalsis or an excessive accumulation of flatus or strain in a constipated person due to an effort to evacuate the bowel. Indeed in many cases the exciting factor is so insignificant that it cannot be discovered from the history of the case. Even a sudden change in the attitude of the patient has brought it about.

The extent of the rotation varies from a half turn to two or even three complete turns. It generally takes place from right to left, that is in the direction of the hands of a clock. The position of the bowel after volvulus varies considerably. Where the rotation takes place with the loop more or less in the pendulous position, and if the case is seen early, the volvulus lies mostly in the pelvis in front of or behind the rectum, that is in the lower part of the abdomen and on the left side. If unrelieved, the distension of the bowel increases and the twisted loop, gradually filled up with gas, moves upwards and to the right. With increasing distension of the volvulus the large bowel above the twist also begins to dilate, and in a short time the whole abdomen is enormously distended and respiratory embarrassment is noted.

When the twist takes place with the loop already dilated and lifted out of the pelvis by gas, the volvulus occupies most of the left side of the abdominal cavity with only partial encroachment on the right side and into the pelvis. In either case the coils of small intestine are collapsed by compression.

In certain cases the distension of the bowel is so considerable that the longitudinal muscular bands cannot be recognized.

If the twist is complete and tight so that there is almost total disturbance of circulation which occurs in most cases, the changes in the wall of the loop are rapid, and the wall becomes cedematous and congested. Hæmorrhage from minute vessels in its walls takes place and exuded serum and blood dilute any faecal matter that may be present. With further progress of the constriction, effusion of sero-sanguinous fluid into the general peritoneal cavity may occur. This has been stated by some authorities as diagnostic but in my experience it is rare and I have so far noticed it only in one case. If the volvulus is still unrelieved, patches of ulcer appear in the mucous membrane of the bowel and later small areas of gangrene are noticeable on the serous coat. I have seen both these conditions but I have never seen perforation even in very advanced cases. Perforation when it does occur is usually said to be found above the obstruction.

The gas which fills the distended bowel is certainly the result of putrefactive processes, which follow the condition. A puncture of the bowel leads to the escape of an offensive gas and some fluid fæces.

When the twist is not complete and not very tight, the distension is not so extreme and some fluid fæces mixed with blood and flatus may be passed.

The onset of the disease is always sudden and is ushered in with a fairly sharp pain in the region of the left iliac fossa followed by absolute constipation. In the early stages the pain in the iliac fossa is from time to time augmented by colicky exacerbations. The dilatation is so rapid that soon pain and tenderness are complained of all over the abdomen. This, however, is inconsiderable and of an indefinite character and is, I think, due to the tremendous dilatation putting the serous coat of the bowel and its mesenteric attachments on the stretch. The dilatation causes a drum-like note on percussion. Absolute constipation and the sudden sharp pain, which mark the onset of the disease in a patient who is habitually constipated, are important points in diagnosis. The initial pain in the iliac fossa and its colicky exacerbations last only for a very short time and thus I have been able very rarely to elicit this history from a patient.

Early cessation of colic is no doubt due to early muscular paralysis of the large intestine, and this is proved by the fact that even in a case seen in the early stages, when, on untwisting the volvulus, the flatus tube is passed, the escape of gas is purely mechanical and has to be helped by gentle pressure on the gut. The collapsed bowel after evacuation still retains its abnormally large calibre, and is helpless for days to evacuate whatever may be drained into it from the small intestine. When this is remembered it will be realized how important it is in post-operative treatment to evacuate the bowel by lavage and flatus tube for some time afterwards.

Complete disappearance of pain and tenderness over the abdomen I have found a very bad omen. The pain generally disappears with the onset of gangrene and such cases always prove fatal.

Toxæmia is rather slow in onset as compared with other varieties of acute intestinal obstruction, no doubt owing to very slow absorption as a result of almost complete obstruction of arterial, venous and lymphatic circulation.

The temperature remains normal till very late in the condition when it may become sub-normal. The pulse rate and respiration in the early stages are also practically normal. Indeed I have often noticed the pulse rate and respiration to be slower than normal. But with increase in abdominal distension late in the course of the disease respiration becomes more frequent while the pulse rate is only slowly

PHRYNODERMA : A CONDITION DUE TO VITAMIN DEFICIENCY

By LUCIUS NICHOLLS, M.D., B.C., B.A. (Cantab.)
Director of Pasteur and Bacteriological Institutes,
Ceylon

THE symptoms, pathology, course and complications of such deficiency diseases as pellagra, beriberi, and scurvy are well defined, even if the final details of their ætiologies have not been decided. But these are conditions which are familiar to many medical men who work among the indigent classes of the tropics and to which they refer by such indefinite terms as marasmus, malnutrition, deficiency dermatoses, diarrhœa and dysentery due to bad food.

Many years ago in East Africa I was concerned medically with gangs of African labourers working on the construction of the Magadi Railway and the Magadi Soda Factory. These labourers were recruited from their villages, more or less as indentured labour, for a period usually of three months. The healthy only were recruited. They arrived with healthy shining skins. They worked hard for long hours building embankments, etc. The majority of them were fed on maize meal only, it was called *poocho*, and there were few, if any, means by which they could augment this diet.

(Continued from previous page)

descending part of the duodenum. The right testis hangs a quarter of an inch lower than the left.

We have not found any antero-posterior transposition of the viscera. Such a specimen showing general transposition of the viscera with a tricoelian heart described by Adrian Stokes, of Trinity College, Dublin, in the *Journal of Anatomy and Physiology*, 1909, page 301, is of particular interest. A newly born, well-developed male child lived only for a few minutes and died in spite of artificial aid. On post-mortem examination, it was found that in addition to the general transposition of the viscera in the lateral plane, there was also antero-posterior transposition only with regard to the ascending aorta and the stem of the pulmonary artery, so that the ascending aorta was situated in front and to the left of the pulmonary artery. The heart showed only three chambers, two auricles and a common ventricle. The common ventricle was divided by an incomplete septum into two unequal parts, a large right and a small left. Both the aorta and the pulmonary artery opened into the left part of the ventricle, whereas the right part communicated with the pulmonary (right) auricle through the auriculo-ventricular orifice. The pulmonary (right) auricle communicated with the systemic (left) auricle through the foramen ovale and the systemic auricle had no direct communication with the common ventricle.

Within a few weeks their skins lost the natural gloss, and a close inspection showed dry goose skin due to enlargement of the sebaceous glands. They became emaciated, the papules of the skin enlarged, and the epidermis became dry and furfuraceous, a mild form of neuritis was common among them, diarrhœa set in and in many cases was soon followed by death. A similar disease was prevalent among the porters of the Carrier Corps during the war in East Africa. Such a term as marasmus, general debility or dysentery was considered a sufficient description of the cause of death.

I think this picture will be familiar to others who have had experience of gangs of improperly-fed native labourers.

Recently I inspected a jail with a population of over 1,500 prisoners where there was an outbreak of a skin eruption, often accompanied by signs of neuritis, xerophthalmia or keratomalacia, and diarrhœa or dysentery.

There were 87 patients in the prison hospital and the majority of them had papular dry skins. There were 19 in the advanced stages of this, all had diarrhœa or dysentery, and neuritis in a mild or advanced form, and 11 of them showed signs of keratomalacia.

The medical officer stated that the patients did not usually recover from this advanced condition, and that it was customary to consider that death was due to dysentery.

This preliminary inspection indicated the necessity for detailed enquiry into the conditions existing in the prison. The prison authorities kindly supplied the following table of statistics:

TABLE I
Death rate and sick rate in the prison*

	DAILY AVERAGE SICK		DAILY AVERAGE NUMBER OF PRISONERS IN JAIL		DEATHS IN PRISON HOSPITAL	
	Prison hospital	Prison dispensary	Convicted	Unconvicted	Dysentery	Other diseases
1931 ..	75.92	92.4	1,220.4	37	26	28
1932 ..	97.8	120.4	1,463.8	47	40	21

* Needless to state executions are not included in the above statistics (table I).

The sick rate is high and this is reflected in the death rate of 43 per 1,000 for 1931 and 40 per 1,000 for 1932.

The true death rates are higher than these figures indicate, because prisoners who are suffering from incurable diseases and are considered likely to die are sometimes pardoned and discharged to their homes. During 1932 nineteen prisoners were medically boarded for this purpose and recommended for discharge, but, before

COMPLETE TRANSPOSITION OF THE VISCERA

By T. SESHACHALAM, L.R.C.P. (Lond.), M.R.C.S. (Eng.)
Professor of Anatomy, Mysore University

and

K. KRISHNA RAO, B.Sc., M.B., B.S.
Lecturer in Anatomy, Mysore University

THE body of a boy, aged two years, who died in the hospital of infantile biliary cirrhosis was dissected in the Mysore University Medical College. This body showed complete trans-

position in the lateral plane of both thoracic and abdominal viscera, the picture presented being an exact mirror image of a normal body.

(Continued from previous page)

hypodermic injection of morphine and atropine. Use of general anaesthetics such as chloroform or ether often brings about pneumonia and a fatal result in a case already toxæmic. The twisted loop of bowel is generally quite insensitive even when its mesentery is stretched or the loop itself squeezed in the course of the operation. Where there is considerable mental uneasiness and the patient demands chloroform or ether anaesthesia an ether mask put over the face often suffices to quieten the nervous patient.

I have performed the operations described above (lateral anastomosis with fixation of the upper or lower limb to the lateral parietal peritoneum) in several cases without recurrence.

Such abnormalities though recorded by various authors are rare, and we are reporting this case as it is the first complete transposition met with by us in the dissecting room.

Cardio-vascular system.—The heart, with the apex pointing to the right, is situated on the right side of the chest with its cavities similarly transposed. The ascending aorta is situated to the left of the pulmonary artery, in the normal slightly posterior plane, the arch of the aorta running from left to right and the descending thoracic aorta running along the right side of the vertebral column. The innominate artery divides into the left common carotid and the left subclavian arteries; the right common carotid and the right subclavian arise independently to the right of the innominate. The right innominate vein obliquely crosses the great vessels superficially from right to left and joins the left to form the superior vena cava which is situated to the left of the median plane. The inferior vena cava is situated on the left of the vertebral column and the two venæ cavæ open into the left atrium.

Respiratory system.—The right lung has only two lobes and presents the cardiac notch along its anterior border. The left lung does not clearly show three lobes, as would be expected.

Digestive system.—The liver (which is much enlarged by disease) is situated on the left side with the larger lobe to the left. The structures in relation to its visceral surface are transposed. The fundus of the stomach is situated on the right side of the cardiac opening which is itself situated to the right of the median plane. The pyloric end is directed to the left and joins the duodenum. The duodenum commences on the left side, has its concavity directed to the right, enclosing the head of the pancreas, the duodeno-jejunal flexure being situated at the level of the second lumbar vertebra to the right of the median plane. The mesentery is attached to the posterior abdominal wall along a line running from the right side of the second lumbar vertebra to the left sacro-iliac articulation. The cæcum is situated in the left iliac fossa with the appendix attached to its right side, about three-fourths of an inch below the ileo-cæcal junction, the free border of the meso-appendix having its concavity directed to the right. The ascending colon and the hepatic flexure are situated on the left side, the splenic flexure and the descending colon being situated on the right, and the sigmoid colon situated on the right side of the pelvic cavity ends in the rectum. The spleen is situated in the right hypochondrium with its hilum facing the left side. The remains of the thymus are present in the superior mediastinum superficial to the great vessels.

Genito-urinary system.—The left kidney is situated half an inch lower than the right kidney and its hilum is in relation anteriorly with the

(Continued at foot of opposite page)

Prison dietary

Unconvicted prisoners are placed in the remand jail, and their daily diet is as follows :—

Rice, 22 ounces.
Fresh fish, 2½ ounces, 1½ ounces when cooked.
Or Dried fish equivalent in weight of fresh fish.
Plantain, 2 ounces.
Vegetables, 2 ounces.
Sugar, ½ ounce.
Coconut, ½ ounce.
Lime, ½.
Onions, ½ ounce.
Chillies, 2.
Pepper, 1/10 ounce.
Salt, ½ ounce.

A prisoner after conviction is placed upon a diet known as penal no. 1 for the first 14 days of his imprisonment. Penal no. 2 is served to him for the next 14 days. Thereafter for 11 months he receives ordinary no. 1. After he has served for one year he receives ordinary no. 2 for the remaining period of his sentence.

The following are the diets :—

Penal no. 1

Bread, 4 ozs.
Rice, 18 ozs.
Vegetables, 4 ozs.
Coconut, ½.
Lime, ½.
Pepper, 1/10 oz.
Salt, ½ oz.

Penal no. 2

Bread, 4 ozs.
Rice, 18 ozs.
Plantain, 2 ozs.
Vegetables, 2 ozs.
Dhall, 2 ozs.
* Jaggery, ½ oz.
Coconut, ½.
Lime, ½.
Onions, ½ oz.
Chillies, 2.
Pepper, 1/10 oz.
Salt, ½ oz.

Ordinary no. 1

Bread, 4 ozs.
Rice, 18 ozs.
Fish, 2½ ozs.
Plantain, 2 ozs.
Vegetables, 2 ozs.
Dhall, 2 ozs.
* Jaggery, ½.
Coconut, ½.
Lime, ½.
Onions, ½ oz.
Chillies, 2.
Pepper, 1/10 oz.
Salt, ½ oz.

Ordinary no. 2

Bread, 4 ozs.
Rice, 18 ozs.
Beef or liver, 2 ozs.
Fish, 2 ozs.
Plantain, 2 ozs.
Vegetables, 2 ozs.
Dhall, 2 ozs.
* Jaggery, ½ oz.
Coconut, ½.
Lime, ½.
Onions, ½ oz.
Chillies, 2.
Pepper, 1/10 oz.
Salt, ½ oz.

* Palm sugar.

The following table gives the constituents of the three meals a day for the four diets :—

Meal	Penal no. 1	Penal no. 2	Ordinary no. 1	Ordinary no. 2
Early morning ..	Bread and cunjee, 4 ozs. (Rice gruel).	Bread and cunjee, 4 ozs. Jaggery.	Bread and cunjee, 4 ozs. Jaggery.	Bread and cunjee, 6 ozs. Jaggery.
Mid-day ..	Rice and vegetables.	Rice and vegetables.	Rice and vegetables.	Rice and vegetables.
Evening ..	Pepper water which is made by boiling pepper, salt and tamarind in water.	Rice and vegetables, 8 ozs.	Rice and vegetables, 8 ozs. Fish, 2 ozs.	Beef, 1½ ozs. Rice and vegetables, 6 ozs. Fish, 2 ozs.

The monotony of these diets is somewhat varied in practice, as follows :—

Ordinary no. 1

Mondays—2 ounces of red onions, no fish.
Tuesdays—2½ ounces of fresh fish.
Wednesdays—2 ounces potatoes.
Thursdays—dried fish.
Fridays—2½ ounces of fresh fish.
Saturdays—dried fish.
Sundays—2 ounces potatoes, no fish.

Ordinary no. 2

This is the same as the above, but 1½ ounces of cooked meat is given every day except Friday.

The vegetables consist principally of the following :—One of three varieties of pumpkin is supplied twice a week, and a variety of the following is supplied, according to which are in season, on the other five days :—cucumber, brinjals, snake gourds, jack fruit, bread fruit, bandakka, or drum sticks. Cabbages, tomatoes, spinach and beans have been supplied very occasionally, about once in three months, according to the cooks' statements.

The quantity and quality of the vegetables is such that the diet cannot contain much fat-soluble vitamin. It is probable that there is also a deficiency in B₂.

The penal diets nos. 1 and 2 are particularly deficient. One green plantain weighs between 3½ to 6 ounces and when skinned weighs 2 to 4 ounces. Therefore the amount of vegetables served to each prisoner daily is about the equivalent of one plantain or less.

Most of the prisoners come from the indigent classes, among whom papular dry skin and keratomalacia is not uncommon; therefore it is not surprising, when after conviction they are placed on these diets, that they soon show signs of vitamin deficiency, for the reserves of vitamins in their bodies cannot be high.

Ordinary diet no. 1 differs from the penal diets principally by the addition of a small amount of fish. White fish is usually supplied and this contains very little vitamin A or D (McCarrison, 1921).

The prisoners who have been in prison more than 18 months are less affected than those who have been imprisoned for a shorter period. Probably the addition of the beef which is supplied in ordinary diet no. 2 accounts for this. And this diet may be sufficient to maintain a

effect could be given to this, six died; the remaining 13 were discharged. Furthermore, the aged and infirm are not retained at this prison, but are sent to a small prison at Negombo.

The death rate in Ceylon for the ten years 1921—1930 was 26.2 per 1,000. But the death rate for the Western Province, in which the prison is situated and where malaria is not prevalent, has always been less than this, and in 1932 it was 16.8 per 1,000.

The death rate of a general population is largely determined by infant mortality and the deaths of the aged; both these factors are absent from this prison, and therefore the death rate should not be more than half that of the surrounding population. Thus the death rate in the prison is at least 5 times as high as it should be.

The enquiry was especially directed to skin diseases, neuritis, eye diseases, diarrhoea and dysentery. The medical officer supplied the following table showing the number of prisoners who were treated for these symptoms in 1931 and 1932 :—

TABLE II

		1931	1932
<i>Dysentery.</i> Prison hospital.	Amoebic	38	41
	Bacillary	248	476
	Others	288	246
<i>Dysentery and diarrhoea.</i> Welikada jail. ..		8,359	15,874
<i>Eye diseases.</i> Prison hospital. .. (Keratitis and corneal ulcer.) Welikada jail. .. (Eye diseases.)	..	79	99
	..	1,837	5,866
	..	1,928	7,261
<i>Skin diseases.</i> Prison hospital. .. Welikada jail. ..		237 1,928	151 7,261
<i>Neuritis.</i> Prison hospital. .. Welikada jail.	5	41
	..	1,872	2,397

Although these statistics show the surprising incidence of these conditions, they are even more prevalent than these figures indicate because the diagnosis is given on the predominant symptoms only. For instance the patients in hospital with advanced dry skin, neuritis, keratomalacia and dysentery are considered to be suffering from dysentery and the other symptoms do not appear in the returns. Twenty-one patients being treated for marked keratomalacia were examined, and every one showed signs of papular dry skin.

Examination of working prisoners for papular dry skin and keratomalacia

The method of examination was to line up the prisoners and examine each one and call out the result which was written down by the apothecary of the prison hospital. The prisoner then passed to the apothecary who noted down the date when he entered prison; in this way all bias from a knowledge of the length of time each person had been in prison was avoided. Some of those of the first gangs which were examined complained of burning sensations in the hands and of numbness, tingling and weakness in the legs; others complained of dimness of sight and other symptoms referable to the eyes. But an enquiry into the subjective symptoms of prisoners is an arduous procedure pregnant with error, therefore it was avoided.

The various gangs of prisoners examined were, (a) in the remand jail where they sometimes remain for several months; (b) working in the coir fibre sheds; (c) working in the carpentry shops; (d) working in the laundry.

In the following table (table III) the patients are placed in one of four categories :—

Category I includes those who have been in the prison for less than one month.

Category II includes those who have been in the prison for more than one month and less than one year.

Category III includes those who have been in the prison for one year to 1½ years.

Category IV includes those who have been in the prison for more than 1½ years.

TABLE III

			Total examined	Papular dry skin	Papular dry skin and kerato- malacia	Kerato- malacia only	Skin and eyes more or less healthy	Percentage show- ing papular dry skin and/or keratomalacia

person in a fair state of health provided he is not given very hard work.

Overcrowding.—The cells and corridors were built to accommodate fewer prisoners than are in the jail at present. There is some overcrowding of the floor space at night, but this is mitigated by the great height of most of the corridors.

THE SYMPTOMS

Papular dry skin.—This commences with the appearance of minute, hard papules, and the surface of the skin becomes dry and loses its natural gloss. The eruption may be irritable and the patients rub and scratch the skin. The papules may occur on any part of the body, but they are particularly liable to occur on the thighs, the extensor surfaces of the arms near the elbows, the abdomen and across the shoulders. They are less common on the face, neck and anterior surface of the chest.

The papules enlarge and many of them become very dark in colour. When examined with a lens the apex of a papule is seen to have a small crater-like opening often with minutely fissured sides. When a papule is squeezed with forceps a dense somewhat-translucent sebaceous material exudes; in some cases this material cannot be squeezed out without incising the papule.

In the later stages the natural fissures of the skin increase in depth and width, and still later the whole skin of the body becomes very dry and furfuraceous, and the papules stand out with dark pigmented areas around them.

The papules do not tend to suppurate, but a dry form of skin sepsis may take place, when hard dry thin scabs form over and around the papules. Removal of a scab leaves a very superficial excoriation of the skin.

The papules are enlarged sebaceous glands plugged with altered sebum. The papules in some cases appear to spread laterally, producing sub-angular, slightly-raised flattened areas of smooth epidermis, contrasting with the surrounding accentuated fissures of the skin; the centres of the areas show the openings of the gland ducts, possibly this is a process of recovery.

In some cases the furfuraceous dry skin is more marked than the eruption of papules, but the latter can always be seen by a close inspection.

The diagnosis of the papular dry skin must be made from scabies and acne.

It is liable to be mistaken for scabies in those patients where there is itching. The distribution of the two conditions is different, scabies occurs between the fingers, on the front of the elbows, around the nipples and on the buttocks; it is seldom so widely spread as the condition of papular dry skin. Scabies is at first vesicular, and later becomes pustular, and the eruptions

due to the sepsis and scratching are not as dry as in papular dry skin.

In acne the itching is more or less absent, and the material squeezed from an acne papule is white, opaque, and caseous in contrast to the somewhat translucent material of papular dry skin. Well-developed acne sooner or later becomes papular, and the sepsis often spreads around the base of the affected gland and forms a small abscess. But this I have not seen in papular dry skin.

Some of the prisoners had pyosis, that is a septic condition of the hair follicles, its commonest site is on the extensor surface of the legs below the knee. It cannot be mistaken for papular dry skin.

The photographs reproduced here are from two early cases and one later case. Many of the papules were darker than these photographs indicate.

Keratomalacia, due to vitamin-A deficiency, is well known in Ceylon. It has been described from India, Africa, and other countries, and I read in the limited references available that it usually starts as a xerophthalmia.

The course of the disease in the prison appears to be as follows:—It starts by injection of the vessels running from the inner and outer canthi of the eye to the cornea; and the redness of the vessels stands out in marked contrast to the whiteness of the sclerotics; at the same time yellowish thickenings occur where the vessels disappear at the corneal-sclerotic junction.

The next change is the appearance of pin-point opacities in the cornea; these increase in size and may become two or three millimetres in diameter. Then the opaque areas ulcerate, and if the ulcers do not heal they become extensive and hypopyon develops, and finally the anterior chamber and cornea become disorganized and permanent blindness follows.

Before the opacities of the cornea have appeared many of the prisoners complain of dimness of vision and even of blindness. The visual symptoms must be due to the deficiency affecting other parts of the eye than the cornea.

Neuritis.—Table II shows that the diagnosis of neuritis was made in the cases of 41 patients admitted to the prison hospital (apart from those with dysentery and neuritis) and 2,397 patients attending the prison dispensary in 1932.

All the patients in the hospital who had advanced papular dry skin, wasting, diarrhoea and dysentery showed signs of neuritis, and in several cases it was so advanced that the patients were unable to stand. But many of the dispensary patients have subjective symptoms only, namely a burning sensation of the hands, and weakness, numbness and tingling of the legs. The more advanced cases showed absence of knee jerks.

A NOTE ON THE VALUE OF THE ASCITIC FLUID FOR THE WASSERMANN REACTION AND AGGLUTINATION TESTS WITH DYSENTERY ORGANISMS*

By M. V. RADHAKRISHNA RAO, M.D., B.S.

Research Fellow, Andhra University

(From the Department of Pathology and Bacteriology, Medical College, Vizagapatam)

THE material in this paper was collected during an investigation into the causation of ascites (Radhakrishna Rao, 1932) and subsequently during a study on decompensated portal cirrhosis, in the medical wards of the King George Hospital, Vizagapatam.

In all the patients who were admitted with ascites into the medical wards of the King George Hospital, Vizagapatam, the Wassermann reactions and the agglutination tests (with dysentery organisms), of the blood and ascitic fluid, were done as a routine, in addition to the other investigations. This short note is based on a study to find out how far the results obtained with ascitic fluid are valuable in these tests, as compared with those obtained from the blood serum.

The results are summarized in tables I and II. In most of the cases specimens of the blood and the ascitic (aseptically drawn) were taken for examination at the same time; while in the others, there was only a short interval between

(Continued from previous page)

The disease occurs in young children, and although neuritis is not mentioned it is probably the same condition as occurs in the prison.

It appears to me that some name is required for this disease. The name *mandama* (pronounced mārndārmār) is almost synonymous with marasmus and therefore is unsuitable.

Dr. Fonseka's mention of a 'frog-like skin eruption' at first puzzled me, because a frog's skin is soft and smooth. Apparently it is a native description of the eruption, and in translating it into English, he has used the word frog, when it should be toad. The skin of a toad is dry, and 'papular', and the feel and appearance of it are very similar to the later stages of papular dry skin.

The disease may have been definitely named previously, but, if it has not, I propose to call it phrynoderma (φρυνη a toad), and to define it as:—'A papular dry skin eruption frequently accompanied by a mild neuritis and (or) eye symptoms such as night blindness, dimness of sight, xerophthalmia, or keratomalacia; the patients are very liable to diarrhoea or dysentery, when this occurs the neuritis becomes more marked; a high mortality results. The disease is due to vitamin-A deficiency, but other food factors may be at fault'.

* Rearranged by Editor.

the examination of the blood and the ascitic fluid.

It will be seen that out of the 60 cases, in which the Wassermann reactions of the blood and the ascitic fluid are compared, the results of the latter tally exactly with those of the former in 37 cases. However, if the ++ and + results and the (±) and —ive results, respectively, are grouped, it will be seen that there is agreement in 51 out of 60 cases.

TABLE I

Showing the comparative results of the Wassermann reaction of the blood and ascitic fluid. [++ = strong positive; + = positive; (±) = doubtful; — = negative]

BLOOD WASSERMANN RESULTS IN GROUPS		ASCITIC FLUID RESULTS OF EACH GROUP

		—	4
+	12	++	5
		+	6
		(±)	1
		—	0
(±)	3	++	1
		(±)	1
		—	1
—ive	14	++	1
		+	1
		(±)	1
		—ive	11
TOTAL	60	..	60

Table II, given below, shows that out of the 53 cases in which the results of the agglutination tests (with dysentery organisms) of the blood and ascitic fluid are compared, 22 cases showed the same reaction in both. Out of these 22 cases, 16 showed negative reaction both to *B. dysenteriae* (Shiga) and *B. dysenteriae* (Flexner).

Out of the 31 cases in which the agglutination reactions of the ascitic fluid did not agree with those of the blood, 5 gave a higher reaction than the blood serum, while in the remaining 26 cases the reaction was in a very low titre compared to that of the blood serum, or negative altogether.

It will thus be seen that, while the results of the Wassermann reactions of the ascitic fluid compare favourably with those of the blood

Bacillary dysentery is a prevalent infection in the prison, and the possibility of the neuritis being due to dysentery was considered. This possibility cannot be excluded in some of the advanced cases in the hospital, although it is very improbable that such a complication of dysentery would occur in all these cases.

But the milder forms of neuritis so common in the prison cannot be due to dysentery, because very few of the patients had had dysentery.

The neuritis closely resembles that of pellagra in its insidious onset.

Diarrhœa and dysentery.—Although there can be little doubt that the papular dry skin, the keratomalacia, and the neuritis are due to vitamin deficiency, the diarrhœas and dysenteries cannot be definitely assigned to this cause. Flexner's bacillus has been isolated from the stools of many patients and the overcrowding of the prison may account for the prevalence of bacillary dysentery.

It is generally accepted that persons who live on a diet deficient in the fat-soluble vitamins are particularly liable to bacterial infections, and these infections are generally very acute.

Monkeys and rats fed on vitamin-deficient diets develop persistent diarrhœa, which as death approaches becomes dysentery.

One of the three cardinal signs of pellagra is diarrhœa.

The course of the disease.—The disease commences as a papular dry skin, and usually there are subjective symptoms of mild neuritis, the patient loses weight, but does not become markedly emaciated. Diarrhœa or dysentery starts, and usually becomes very acute, pyrexia is low, and the temperature seldom rises above 101°F. The skin eruption becomes accentuated, and the neuritis increases, and in two-thirds of the patient's eye symptoms occur. Some of the patients die a few days after the onset of the acute dysentery, but with most of the patients the dysentery becomes chronic, and periods, when the stools become normal, alternate with recurrences of the diarrhœa. In the last stages the patient becomes very emaciated, and is unable to use his legs or arms, the skin becomes very dry and furfuraceous, xerophthalmia or keratomalacia is present, and in a few cases symptoms of dementia occur.

Prognosis is difficult because, although most die, some recover, and others when apparently well on the way to recovery die suddenly.

Post-mortem examinations.—Two post-mortem examinations have been obtained.

A man about 50 years of age was admitted to the hospital with acute bacillary dysentery (Flexner). He was not emaciated, but had papular dry skin and a few opacities in the eyes from keratomalacia. The attack was fulminating and he died in five days.

The post-mortem examination showed the heart, lungs and kidneys to be normal, the spleen weighed 3½ ounces and the liver 40 ounces, the latter showing fatty degeneration. The large intestine showed advanced diffuse coagulative necrosis throughout its length, and the last two feet of the ileum was affected. Obviously this man died of acute bacillary dysentery. But a man of this age would not pass through life in a country where bacillary dysentery is common without acquiring some immunity to the disease, and it is probable that the food deficiency of which he showed symptoms was the primary cause of his loss of immunity.

The second post-mortem examination was carried out on the body of a man who had been in hospital for six weeks. He had had dysentery, and his later symptoms were diarrhœa, advanced papular dry skin, neuritis—he had been unable to stand or feed himself, and had xerophthalmia, emaciation, and signs of dementia. The diarrhœa had ceased several days before death.

The post-mortem findings were:—lungs normal; the heart was carefully examined for fatty degeneration but this was not apparent. The liver showed fatty degeneration and weighed 35 ounces; the spleen weighed 3 ounces; the kidneys showed signs of early 'granular contraction'. There were areas in the large intestine where dysenteric ulcers had healed, but the rectum contained formed faeces free of mucus. The walls of the small intestines were thin and the mucous membrane showed slight superficial erosions, somewhat resembling the condition seen in pellagra.

Had the history of the patient been unknown, it would have been impossible to have stated from the post-mortem findings the cause of death.

Discussion.—Keratomalacia has been described frequently as a symptom of vitamin-A deficiency. But in the literature to which I have access I cannot find references to papular dry skin, associated with neuritis and diarrhœa or dysentery, attributed to vitamin deficiency.

Dr. D. C. de Fonseka, Medical Officer of Health, recently sent to me a short note on a paper which he read before the Ceylon Society of Medical Officers of Health.

He was discussing the Registrars' returns of deaths from rickets. He states that 'it is not true rickets', but is a condition which the local inhabitants call *mandama*. He writes:—'The name *mandama* is given to a condition characterized by eye changes "keratomalacia and xerophthalmia", night blindness, general stunting of growth, frog-like skin eruption, frequent motions with sometimes prolapse of the rectum. There are no bone changes present. The eye condition if untreated leads to blindness'.

A NOTE ON THE VALUE OF THE ASCITIC FLUID FOR THE WASSERMANN REACTION AND AGGLUTINATION TESTS WITH DYSENTERY ORGANISMS*

By M. V. RADHAKRISHNA RAO, M.A., B.S.

Research Fellow, Andhra University

(From the Department of Pathology and Bacteriology, Medical College, Vizagapatam)

THE material in this paper was collected during an investigation into the causation of ascites (Radhakrishna Rao, 1932) and subsequently during a study on decompensated portal cirrhosis, in the medical wards of the King George Hospital, Vizagapatam.

In all the patients who were admitted with ascites into the medical wards of the King George Hospital, Vizagapatam, the Wassermann reactions and the agglutination tests (with dysentery organisms), of the blood and ascitic fluid, were done as a routine, in addition to the other investigations. This short note is based on a study to find out how far the results obtained with ascitic fluid are valuable in these tests, as compared with those obtained from the blood serum.

The results are summarized in tables I and II. In most of the cases specimens of the blood and the ascitic (aseptically drawn) were taken for examination at the same time; while in the others, there was only a short interval between

(Continued from previous page)

The disease occurs in young children, and although neuritis is not mentioned it is probably the same condition as occurs in the prison.

It appears to me that some name is required for this disease. The name *mandama* (pronounced mārndārmār) is almost synonymous with marasmus and therefore is unsuitable.

Dr. Fonseka's mention of a 'frog-like skin eruption' at first puzzled me, because a frog's skin is soft and smooth. Apparently it is a native description of the eruption, and in translating it into English, he has used the word frog, when it should be toad. The skin of a toad is dry and 'papular', and the feel and appearance of it are very similar to the later stages of papular dry skin.

The disease may have been definitely named previously, but, if it has not, I propose to call it phrynoderma (φρυνη a toad), and to define it as:—'A papular dry skin eruption frequently accompanied by a mild neuritis and (or) eye symptoms such as night blindness, dimness of sight, xerophthalmia, or keratomalacia; the patients are very liable to diarrhoea or dysentery, when this occurs the neuritis becomes more marked; a high mortality results. The disease is due to vitamin-A deficiency, but other food factors may be at fault'.

the examination of the blood and the ascitic fluid.

It will be seen that out of the 60 cases, in which the Wassermann reactions of the blood and the ascitic fluid are compared, the results of the latter tally exactly with those of the former in 37 cases. However, if the ++ and + results and the (±) and —ive results, respectively, are grouped, it will be seen that there is agreement in 51 out of 60 cases.

TABLE I

Showing the comparative results of the Wassermann reaction of the blood and ascitic fluid. [++ = strong positive; + = positive; (±) = doubtful; — = negative]

Table II, given below, shows that out of the 53 cases in which the results of the agglutination tests (with dysentery organisms) of the blood and ascitic fluid are compared, 22 cases showed the same reaction in both. Out of these 22 cases, 16 showed negative reaction both to *B. dysenteriae* (Shiga) and *B. dysenteriae* (Flexner).

Out of the 31 cases in which the agglutination reactions of the ascitic fluid did not agree with those of the blood, 5 gave a higher reaction than the blood serum, while in the remaining 26 cases the reaction was in a very low titre compared to that of the blood serum, or negative altogether.

It will thus be seen that, while the Wassermann reactions of the blood compare favourably with those

serum, the results of the agglutination tests (with dysentery organisms) do not, a lower titre than that of the blood serum or a negative result being obtained in most of the cases.

Summary and conclusions

The results of the Wassermann reactions and the agglutination tests (with dysentery organisms), of the blood and the ascitic fluid, collected in a series of unselected cases of ascites, in the medical wards of the King George Hospital, Vizagapatam, are compared in this paper. It is pointed out that, while the results of the Wassermann reactions of the ascitic fluid compare favourably with those of the blood serum, the results of the agglutination tests (with dysentery organisms) do not, a lower titre than that of the blood serum, or a negative result, being obtained in most of the cases.

I wish to express my thanks to Rao Bahadur Dr. T. S. Tirumurti, Professor of Pathology, under whose direction this material was collected and to Dr. C. Ramamurti, Professor of Bacteriology, for permission to publish these results.

My thanks are also due to Dr. N. G. Pandalai and the members of the staff of the Medical Unit of the King George Hospital, Vizagapatam, for their kind co-operation during the collection of this material.

A CAUSE OF DAMAGE TO OPTICAL GLASS IN THE TROPICS

By H. W. ACTON, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Director, School of Tropical Medicine and Hygiene, Calcutta

DETERIORATION of the glass of microscope objectives, telescope lenses, prisms and expensive optical glass of all kinds has always been a source of worry to those using optical apparatus in the tropics. Many theories have been advanced to explain this damage, but as far as is known few, if any, of these have ever been definitely proved. In the present investigation, one cause of the clouding of prisms has been definitely established, and a remedy has been suggested. The work is not complete and further research on the lines indicated below will probably produce fresh facts, but it is felt that the matter is of such importance that these notes should be published even in their present state of incompleteness.

Certain prisms were submitted to the writer with a request for an explanation for the clouding of their polished surfaces, which recurred after the glass had been thoroughly cleaned.

The first two prisms submitted showed a fine growth of mycelium on the polished surface; this arose from the region of the unpolished ridge on which there was some wax-like material. Around the hyphæ there was a 'frosted' area which appeared to be formed of deliquescent salts, probably secreted by the hyphæ themselves. In this way the moisture necessary for the existence of the mycelium was produced. Cultures from the hyphæ were made on Sabouraud's and Norris' synthetic media and pure cultures of a *Penicillium* were obtained. Hanging-drop preparations of the hyphæ showed that some of them carried fine conidia or spores arranged in small chains of four or five each which projected as four finger-like processes from the end of the hyphæ. The same growths were seen on the prisms but in these the end-organs of fructification were not so well marked. Four more prisms were received for examination and on these the end-organs could not be seen with a two-thirds objective, but with the corneal lens large spore-like bodies—probably zygo-spores—were seen near the foot of the growth on two of the prisms. The zygospores from these two prisms were inoculated on two tubes and these showed a pure culture of a greenish *Penicillium*.

Inoculation experiments.—Two prisms were sterilized with alcohol and a little lard was smeared on the ridge between the polished surfaces. Spores were inoculated on the ridge and a growth appeared five days later, and after a further eighteen days *Penicillium* was recovered from the prisms. Four other prisms were sterilized and their ridges greased by wiping them with sterile gauze containing grease, they were then inoculated and growth appeared four days later to be followed in a further fourteen days by the appearance of a *Penicillium*. These experiments indicate that the mycelium probably obtains its nourishment from the grease or fat in the mounting material in which the ridge is imbedded, and that it spreads slowly from this point over the polished surface of the prism, the necessary moisture being obtained from the humid atmosphere by the deliquescent salts excreted by the hyphæ.

Tests of different mounting materials.—Lard, grease and beeswax were melted and two agar tubes were smeared with each material, and growth only occurred in the two tubes on which lard was smeared, the other four being negative. Sealing-wax could not be tested in the same way. This experiment indicates that certain fatty substances in lard supply the source of carbon for the fungus, the nitrogen, oxygen and water probably coming from the atmosphere and examination of the prisms with the corneal lens, when first received, suggests that the fungus obtains its nourishment from some fatty matter in the mounting substance. The mycelial growth largely consists of surface runners and

very few conidia, and the formation of zygo-spores shows that the nutriment available for these fungi is very poor.

Tests of the fungicidal properties of various products.—Gentian violet in dilutions of 1/100,000, 1/50,000, and 1/10,000 were first tried, but none had any apparent effect on the growth of the fungus; a dilution of 1/5,000, however, inhibited it for a time but did not entirely prevent the growth.

Copper sulphate in the same dilutions as those used for gentian violet had no inhibitory effect.

Further experiments with 1/1,000 dilutions of gentian violet and copper sulphate were done, and the former inhibited growth for six days whilst the latter had no effect on it.

The essential oils, sandalwood, cinnamon, clove, turpentine and thymol, were tested by making solutions of 1/1,000 strength with 0.1 per cent alcohol as the solvent. A loopful of a three-day-old culture was placed in all of these liquids for the following different periods, half a minute, five minutes, fifteen minutes, half an hour, and forty-eight hours, and the only oil that showed any marked inhibition of growth under these conditions was thymol. Exposure of the fungus to thymol for five minutes caused inhibition of growth for twenty-four hours, and half-an-hour's exposure prevented growth even after forty-eight hours. Cinnamon oil had a similar but slighter effect when the fungus was left in it for one hour. These oils were tested in another way also. Tubes of Sabouraud's medium were prepared which contained dilutions of the various oils in strengths of 1/5,000 and in this case there was complete inhibition with cinnamon oil and partial inhibition with thymol.

Conclusions.—The fungus found growing on the prisms examined is a *Penicillium*.

This fungus can grow on the polished surface of the glass if there are grease spots on it, but it grows more commonly from the unpolished ridge between the prisms where the mounting material is present.

The fungus obtains its supply of carbon from the fatty compounds in the mounting material, and the nitrogen and oxygen are obtained from the atmosphere.

The hyphæ themselves excrete deliquescent salts which during the high humidity in the monsoon enable the fungus to obtain for its growth the very necessary amount of moisture from the atmosphere.

A few substances were tested for their fungicidal properties on this fungus, and of these cinnamon oil was the best, and thymol the next best; the remainder were inert.

THE ANÆMIA OF THE LEISHMANIA-INFECTED HAMSTER

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P.

and

L. R. SHARMA, M.B., B.S., M.R.C.P.E., D.P.H.,
D.T.M. & H. (Cantab.)

(From the Kala-Azar Enquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)

DURING our study of the anæmia of kala-azar, a parallel study—on a much smaller scale—of the red cells and hæmoglobin value of the blood of Chinese hamsters (*Cricetulus griseus*) was carried out at the same time. The reticulated red cells of this hamster are shown in the plate (plate X, facing page 550) accompanying this paper (Napier and Sharma, 1933). These results were not included as we hoped to add further observations, but opportunity has not arisen.

The technique was exactly the same as that used in our study of human blood. All the hamsters had been in captivity for at least a year during which time they had been fed on soaked gram and green-stuff (cabbage or lettuce); the leishmania-infected hamsters had been infected for at least six months and in each case the infection was a heavy one, demonstrable by liver puncture. The total red cell count, the reticulocyte percentage and the hæmoglobin value (on the Tallqvist scale) were estimated in ten normal and in ten infected hamsters; the results are summarized below:—

	Normal hamster	Infected hamster
Total red cells—		
Maximum ..	12,000,000	10,312,000
Minimum ..	9,775,000	6,083,000
Mean ..	10,837,000	7,418,000
Reticulocyte percentage—		
Maximum ..	2.60	9.80
Minimum ..	1.50	4.00
Mean ..	2.08	6.38
Hæmoglobin—		
Maximum ..	78	70
Minimum ..	68	55
Mean ..	72.6	62.0

The anæmia in the hamster is thus similar to, though not so marked as, that in generalized leishmaniasis in man; the mean reduction in the red cell count is only just over thirty per cent, against nearly fifty per cent in man; there is a threefold increase in reticulocytes, against a fivefold increase in man; and the decrease in hæmoglobin is apparently only slight (but little reliance can be placed on these readings). If the colour index of the normal hamster is taken

as unity, then the colour index of the infected hamster is apparently well above unity; this is contrary to the finding in kala-azar in man.

The blood changes, as in man, are very constant and in only two instances was the count more than a million away from the mean.

On the whole it may be said that these few observations support the conclusions arrived at in the above-mentioned study of the anæmia of kala-azar in man.

A Mirror of Hospital Practice

A CASE OF CEREBELLAR TUMOUR

By K. G. GHARPUREY

LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, Belgaum

Y. S., Hindu male, well built, aged 25, Berad by caste, a farmer, was admitted into the Civil Hospital, Belgaum, on 24th July, 1933, for severe headache. He was sent by the patil (headman) of his village, as he used to roll on the ground because of pain in the head. He had received local treatment in the village for three months without any relief.

On admission.—His speech is slow and he walks slowly with a staggering gait. He states that he is losing strength in his right upper and lower limbs. He feels giddy and reels on standing. He states that his vision is failing and that he feels very heavy in the head and has a severe bursting headache. The pain is so intense that he shouts at times. He does not sleep well and has pain and deafness in both ears though there are no signs of external or middle ear disease. There is a coarse nystagmus. Examination of the eyes revealed optic neuritis in both eyes, tending towards optic atrophy in the left eye.

Iodides and bromides with other sedatives gave him no relief. Lumbar puncture was done and 15 c.cm. of clear cerebro-spinal fluid was removed under pressure.

On 17th August, 1933, the patient had an attack of convulsions, resembling epilepsy and died suddenly. At post-mortem examination a white neuroglial tumour of the size of a lemon was found inside the right lobe of the cerebellum. There were no adhesions. A piece of the tumour was sent to the Haffkine Institute, Parel, Bombay, and the report was glioma of the cerebellum. The specimen is preserved to be sent to the B. J. Medical School, Poona.

Headache, vertigo, staggering gait, nystagmus, with optic neuritis—the typical symptoms of a cerebellar tumour—were present.

REMOVAL OF A FOREIGN BODY FROM THE OESOPHAGUS*

By FRANCISCO DIAS

Casa Cirurgica, Dramapur, S. Goa

A CHILD aged four years was brought to me and the following history was given :

She had swallowed one pice some hours before and since that time all food and liquids were immediately vomited. This statement was tested by giving the child some gruel which she was unable to swallow. There was no evidence of interference with respiration.

The coin could be felt in the oesophagus posterior to the trachea about one finger-breadth above the jugular notch. Under chloroform anaesthesia several unsuccessful attempts were made to extract the coin with a pair of long forceps, and it was then decided to try manipulation. The coin was worked upwards by the fingers of the right hand applied externally and when it reached the back of the throat it was easily seized by the fingers of the left hand and removed. Relief was instantaneous and the child experienced no further trouble.

PASSAGE OF A SAFETY-PIN THROUGH THE ALIMENTARY CANAL

By KOKA VENKATA RAMA RAO, L.M. & S. (Mad.),
L.C.P. & S. (Bom.)

Sankar Dispensary, Tenali

A CHILD aged one year swallowed a small brass safety-pin on 8th October, 1933, at 11 a.m.

I gave castor oil one ounce and by 3 P.M. he had three loose motions, but the pin was not passed. At 5 P.M. I administered half an ounce of isaphagul seeds well soaked in water. The next morning he passed a stool mainly composed of round masses the size of a small lime with some faecal matter, and the opened pin was found imbedded in one of these masses.

These seeds are called, English:—Isaphagul or spogel seeds. Telugu:—Isapugolu villulu. Bengali:—Osabgul. Hindi:—Osufgul.

When the seeds are soaked in water they become coated with abundant adherent mucilage or gelatinous substance. I have used these seeds for a long time in chronic constipation.

AN INTERESTING CASE OF COMPOUND DEPRESSED FRACTURE OF THE SKULL

By JAMIAT SINGH, M.B., B.S.

*Assistant Surgeon in Charge, Civil Hospital,
Fatehjang, Attock District, Punjab*

I. K. was admitted into the hospital on 8th August, 1933, at 10 a.m. with two punctured wounds about $1\frac{1}{2}$ inches above the right eyebrow.

The wounds were quite close together, $\frac{1}{2} \times \frac{1}{2}$ of an inch in size and bone deep. The frontal portion of the skull was found fractured and depressed. There was an oedematous swelling round the injuries which occupied an area of $2\frac{1}{2}$ inches. Temperature on admission was normal and pulse 54; the pupils were dilated

and the right conjunctiva chemosed so that the cornea seemed to be lying in a trough. By the evening the swelling of the right eyebrow had extended to both the upper and lower right lids, and the patient was in his right senses.

The patient passed a very restless night; early on the morning of the next day I found him with pulse 40 and in a state of great irritation though the temperature was still normal, but the whole face had swollen and his talk was incoherent.

Operation.—An incision about 4 inches long was made just above the wounds and the skin reflected towards the face. A circular piece of bone $2\frac{1}{2}$ inches in diameter was found depressed.

A small portion of the healthy bone was trephined and removed. On elevating the depressed bone it was found fractured in three pieces. I removed two pieces and found a huge blood clot lying over the membranes of the brain. I removed the clot and washed the membranes with normal saline; in addition there were two linear fractures running upward and downward from the depressed piece. I left the largest of the three pieces of bone and closed the wound.

Next morning the patient was found to have regained his senses. Temperature was still almost normal and pulse 54, and the swelling of the face was subsiding.

For the following five days the patient had a raised temperature and severe pain in the head and he passed very restless nights.

On the night of the 15th the patient suddenly got irritation of the brain and ran out of the ward and after an hour or so he was brought under control.

Next morning the patient had a temperature of 101.6°F . with pulse 80 and he was very much depressed and out of his senses. His talk was quite incoherent and he complained of very severe stabbing pain in the head.

On the 17th I again opened up the wound and found the loose piece of bone I had left had fallen down and was pressing on the membranes and I removed it. For the following four days the patient was in a state of depression, regaining his senses at times but often indulging in meaningless talk. His pulse varied from 84 to 100 and his temperature from 102°F . and 103°F .

On the 22nd of August, the temperature was nearly normal and the patient was sleeping well and regained his senses.

The patient was discharged as cured on 12th September, 1933.

SUPPRESSED MENSTRUATION

By H. DASS, M.B., F.R.C.S. (Edin.)

Medical Officer, Jind City

A FEMALE patient, R. P., aged 15, came to the out-patient department of the Ranbir Hospital, Jind, early in 1931 with the complaint of weakness, pain in the lower part of the back and abdomen, and low fever. The pain had been present for two days and similar attacks of pain had been recurring periodically every month for a year and a half. The pain had been getting worse, each succeeding attack being more intense and lasting longer. At the onset the pain lasted for two days only, but this had increased to five days. The attacks of pain subsided but the weakness and low fever continued for about ten days longer.

* Rearranged by Editor.

Her temperature was 99°F. Her physical development was normal for her age, and there was nothing abnormal in her family history. She had never menstruated. In this part of the country, menstruation usually starts well before the age of fifteen. Suppressed menstruation was therefore considered in making a diagnosis. On abdominal inspection, nothing abnormal was seen, but, on palpation, a fairly tense round mass of the size of an orange was detected in the lower part of the abdomen in the middle line, apparently arising from the pelvis. It was slightly tender, and dull on percussion.

She was admitted as an in-patient, and on vaginal examination the hymen was found to be ruptured. No external os was visible in the vagina, the upper end of which was dome-shaped (diagram no. 1). No nipple-like projection, nor any aperture nor dimple could be seen at the usual site of the external os. Even a

of the abdomen over the site of the tumour did not help, but finally a thin dressing probe was arrested at a spot in the middle line, and when pressure was applied, it slipped upwards and a small stream of tarry blood came out past the probe. This opening was dilated very gradually at first with different sized probes, and then with uterine dilators (Hegar's) up to number 4. The tarry blood continued to escape and sixteen ounces were collected. The probes and dilators passed a distance of five inches into the uterus. Continuous pressure on the abdomen helped much in evacuating the fluid from the uterus.

After operation blood continued to escape for about six days, decreasing day by day in quantity and also changing in colour and consistency. The girl was discharged as cured after ten days.

She was again examined after two years and a half. She had been menstruating regularly

Diag. No 1.

probe detected no opening. Bimanual examination showed that the site of the uterus was occupied by a mass, round and tense, of the size of an orange, tender and giving signs of fluctuation; no other abnormality could be detected in the pelvis.

She was advised to undergo an operation.

Under general anaesthesia with the patient in the lithotomy position the lateral walls of the vagina were retracted and a duck-bill speculum introduced. Nothing but the empty vault of the vagina was seen (diagram no. 1). At first the opening of the uterus was searched for in vain and even strong pressure on the lower part

Diag. No 2.

since the operation and had been feeling perfectly well in every way. Examination revealed a normally-formed external os of the usual shape and size (diagram no. 2). A uterine probe could not be inserted. She was again examined after a few days during menstruation, and the menstrual discharge was seen coming out of the external os, but the uterine probe could still not be inserted.

She was married about two months after the operation, and has not become pregnant yet. The question is whether she can conceive in her present condition, and, if not, will dilatation of the os help her?

Indian Medical Gazette

DECEMBER

ANÆSTHETICS IN INDIA

WE have not been able to trace the record of the first use of true anæsthetics in India—our most easily-available source of such information, the early numbers of this journal, only take us back to 1866—but we have little doubt that it was chloroform that was first used, and that this was introduced very soon after 1847, the year that the British gynaecologist, Sir James Simpson, first employed this anæsthetic. The immediate popularity that chloroform enjoyed has created the impression that it was the first drug introduced for producing general anæsthesia, whereas in actual fact both nitrous oxide and ether had been used for this purpose for some few years before Simpson made his great discovery, the latter anæsthetic actually by Simpson himself who abandoned it in favour of chloroform. Chloroform enjoyed a complete supremacy over its two predecessors, as an anæsthetic for major operations, for many years, but since the beginning of the century its popularity has been steadily waning and to-day in the large hospitals in Europe and America it has been almost entirely replaced by other anæsthetics, amongst which both ether and nitrous oxide figure very prominently.

The explanation of the increasing unpopularity of chloroform is that we are coming to realize more and more that it is not a safe drug. The reason it has taken the best part of a century for this fact to dawn upon the medical profession is not any innate stupidity on their part, but that the safety, or the reverse quality, of a drug, is a matter of comparison. One death due to chloroform in 2,600 operations will not strike the casual observer as a high mortality or as a justification for the appellation 'a dangerous drug', until he compares this with the death rates from ether and nitrous oxide anæsthesia, which even 20 years ago were placed at 1 in 8,000 and 1 in a million, respectively, by a reliable authority; that is to say chloroform is about three times as dangerous as ether and 400 times as dangerous as nitrous oxide. Whereas since its introduction little improvement has been effected in the chloroform itself or in the methods of giving it, there have been very marked advances in the technique of the administration of the other two anæsthetics. Another reason for this showing up of the dangers of chloroform anæsthesia is the improvement in surgical procedure and in the general operation mortality; at a time when the mortality was high an extra death or two, due to chloroform, did not attract much attention.

Furthermore, the safety of an anæsthetic is not the only consideration—though it should be the primary one—and the technically more skilled surgeon demands a corresponding advance in the efficiency of anæsthesia. It might, in fact, be said that the state of surgical advancement of an age, or of a country, was in inverse ratio to the amount of chloroform that was used in its major operations.

A quarter of a century ago some form of inhalation anæsthesia was considered the only possible procedure for major operations in most European and American surgical centres, and the three original anæsthetics—chloroform, ether and nitrous oxide—with the more recently-introduced ethyl chloride, still held the field, though the order of their popularity was being steadily reversed. But since this date there have been many advances; spinal anæsthesia was introduced, had a somewhat chequered early career, but has recently made steady progress; the practice of local and regional analgesia was improved and extended to major operations; and finally the rectal, oral and intravenous narcotics were experimented with and brought to a stage when they could be used with safety, to produce anæsthesia in man.

It cannot be said of the last group of drugs that they have yet reached the stage of perfection, because the variable factor—not in the drugs themselves but in the individual patient—makes the calculation of the *correct dosage* difficult, and necessitates the giving of doses insufficient to keep the patient completely 'under' for any length of time. However, these basal anæsthetics, as they are now called, have proved of immense value in reducing the amount of inhalation anæsthetic that it is necessary to give subsequently, and in abolishing psychic shock almost entirely. From the point of view of the patient this is one of the greatest advances that has been made since the original introduction of chloroform. Instead of having to undergo the terrifying experience of being wheeled to the theatre, meeting other corpse-like or vomiting patients returning to the ward, being frightened by white-clad figures and alarming-looking apparatus, and finally being suffocated into unconsciousness, the patient is given a rectal or intravenous injection, or is merely asked to swallow a draught, passes into unconsciousness in his own bed, and finally recovers to find himself in the same place and the operation over.

India is not usually slow to take advantage of medical advances, but the young surgeon coming to India to take up practice ten years ago must have been very surprised to find that in most hospitals, even in the large towns, chloroform was practically the only anæsthetic used. Some of the reasons for this have been discussed by one of our contributors in this number, so that we will not go into the matter in detail, but undoubtedly the main factor has

been the poverty of the country in general, and of medical institutions in particular. Some of the modern apparatus, for giving gas and oxygen, for example, is very expensive and beyond the means of all but the largest hospitals; hitherto nitrous oxide gas has had to be imported so that the cost for anything more than the amount necessary for short anaesthesia has been prohibitive for hospital use; and the large expenditure of ether entailed in the open method is a serious item. The climatic factor cannot be ignored, but except as far as expense is concerned it has been an excuse rather than a reason; but we do not feel justified in subscribing to Dr. Ganguli's suggestion that the leniency of the coroner is an important factor in determining the use of the most dangerous of anaesthetics.

However, the state of affairs that existed 10 years ago certainly does not exist to-day; as will be seen from a number of contributions that have appeared in this journal during the last year or so, and more particularly from those that will be found in this number, in many of the larger hospitals in India full advantage has been taken of the advances made in other countries, and chloroform is no longer the routine anaesthetic; we hope that the time is not far distant when the newer methods will be in general use even in the smaller hospitals

throughout the country. The excuses for the exclusive employment of chloroform in *mofussil* hospitals are no longer valid, as some of the best anaesthetic procedures do not entail the use of elaborate or expensive apparatus, nor of drugs of prohibitive cost. Furthermore, the choice of anaesthetic agents is a wide one, so that local prejudice—a very important factor and one which varies from district to district in India—can usually be countered; members of the stalwart races of the north, who object to losing consciousness, can be given spinal analgesics, whereas the more highly-strung resident of Bengal can be given a basal anaesthetic. Even here individual fancies can be met; some object to intravenous injections and can have nembutal by the mouth or paraldehyde by the rectum; others insist on them and can be given evipan.

We are publishing in this number of the *Gazette* four papers on anaesthetics by members of the staff of the Medical College Hospitals, Calcutta; two are written by surgeons and two by anaesthetists, and they all deal with the subject from the Indian point of view. No acute divergences of opinion are displayed and all the writers appear to us to support our contention that the use of chloroform in this country should be much more restricted than it is at present.

MODERN METHODS OF ANÆSTHESIA FROM THE SURGEON'S STANDPOINT

By W. L. HARNETT, C.I.E., M.A., M.D. (Cantab.),
F.R.C.S. (Eng.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Surgery, Medical College, Calcutta, and
Surgeon to the College Hospitals

WHEN the writer came out to India in 1907 chloroform was the only anaesthetic available and was used for all purposes. It was supposed to be free from danger in a tropical climate on account of the rapidity of vaporization at high atmospheric temperatures, though whether this is so in the humid atmosphere of the monsoon months is open to doubt. Any advantages it may have possessed on this account were neutralized by the fact that the anaesthetic was usually administered by means of a Junker's inhaler with a vulcanite mask, so that it was practically a closed method, the percentage of chloroform in the inspired air being dependent on the vigour of the pumping and being quite unknown, probably tending to be on the high side. Everyone is familiar with the breath-holding which is produced by the administration of too strong a vapour to the still semi-conscious

patient, followed by struggling and deepening cyanosis, leading eventually to a few deep breaths which carry an unduly strong vapour into the lungs and may result in cessation of respiration, with dilated pupils, clammy dusky colour and a flickering, barely perceptible pulse. Another familiar picture is that of the sudden arrest of the heart's action from commencing the operation before the anaesthesia has reached the third stage, a phenomenon which Levy has demonstrated to be due to ventricular fibrillation, and particularly liable to occur when there is excess of adrenalin in the circulation. The consequent interruption of the proceedings until restorative measures have been successful is very disturbing to both surgeon and anaesthetist and is conducive to an atmosphere of subsequent anxiety which is not compatible with the best surgical work. Even if all goes smoothly the steady fall of blood pressure which takes place during a long operation and the action of chloroform as a protoplasmic poison are big factors in the production of delayed shock, and militate against the patient's chances of recovery. Many patients are lost owing to these causes, who might have been saved by the use of better anaesthetic methods,

the failure of the patient to rally from the operation and his death within a few hours being attributed to his disease and to the severe operation needed, and not to the true cause. For these reasons chloroform is regarded with disfavour by most surgeons except in a very limited class of cases. Nevertheless the comparative cheapness of the method, the simplicity and transportability of the apparatus and the apparent ease of administration cause it to be still regarded with favour in India. The following remarks of Professor Leonard Hill put the position very forcibly:—'Chloroform is a drug used by the young anæsthetist with the utmost hardihood and, until he has had the misfortune in his practice to meet with a death caused by it, he derides the dangers of the drug and asserts that its safety merely depends on the care and skill of the administrator. After losing his patient, he falls to dreading the unavoidable dangers of the drug, dangers which he is now the first to maintain cannot be met by any degree of skill in administration'.

In England in 1907 ether had to a great extent displaced chloroform as the anæsthetic of choice, but it was almost everywhere administered by the closed method with a Clover's inhaler, preceded usually by nitrous oxide gas, to avoid the irritating effects of the ether vapour in the early stages. This is a very efficient and safe method of anæsthesia, but it was never practicable in India, on account of the prohibitive cost of nitrous oxide gas. Closed ether without the preliminary nitrous oxide was used in some hospitals in India in the writer's experience with satisfactory results, though the induction stage was somewhat unpleasant for the patient. It is little more expensive than chloroform as the amount of ether used is small, 4 to 6 ounces sufficing for most operations, it is speedy in action and powerful enough to overcome the most refractory patient. On the other hand the anæsthesia is not very satisfactory especially for abdominal work, as the respiratory movements are very deep from the anoxæmia, relaxation is imperfect leading to difficulty in intra-abdominal manipulations and in closing the abdomen, post-anæsthetic vomiting is worse, and the incidence of pulmonary complications is high. Ethyl chloride may be used in place of nitrous oxide gas for the induction, but is apt to be followed by troublesome vomiting and does not appear to have been much used in India.

Closed ether has now been almost entirely superseded by the open method, in which the air supply is in no way restricted and which requires no more complicated apparatus than is necessary for the administration of chloroform on the open mask. The working margin of safety is much wider than in the case of chloroform, as 16 per cent to 18 per cent of ether in the inspired air is necessary for induction as against 2 per cent to 3 per cent of chloroform. This

involves the use of a large amount of ether, but it may be considerably reduced by the preliminary injection of morphine gr. 1/6 with atropine gr. 1/100, the latter to check the tendency to salivation which is such a troublesome feature of ether anæsthesia. In febrile and toxic cases this is an ideal method, the patient is in a drowsy condition by the time he reaches the theatre, induction is easy and pleasant, the anæsthesia is perfect and there is little vomiting or after-effect. In healthy subjects it may be difficult to induce anæsthesia by this method without the expenditure of considerable time and a large amount of ether, and in such cases it is best to induce by a mixture of chloroform and ether, changing over to ether alone as soon as full anæsthesia is attained. Pure chloroform should not be used for induction if a preliminary injection of morphine and atropine has been given, as this combination causes severe respiratory depression. This is a most excellent and safe method for routine work and in its use the unpleasant accidents referred to above as common with chloroform are never met with, but it has the drawback that in hot climates very large quantities of ether are needed, 12 ounces to one pound for major abdominal procedures. It must also be remembered that in long operations ether has the same action as chloroform, causing a fall of blood pressure and depression of respiration; furthermore its irritating action on the respiratory mucous membranes involves an increased risk of pulmonary complications, only partly checked by the preliminary injection of atropine. In Europe the use of warmed ether vapour is adopted by many anæsthetists to counteract the chilling effects of the cold vapour on the lung alveoli, but the apparatus is complicated and in this climate is hardly necessary. For thoracic surgery and in mouth cases the endotracheal administration of warmed ether vapour under pressure by means of a catheter passed through the larynx has replaced all other methods; the patient is first anæsthetized in the ordinary way, then by the aid of a direct-vision laryngoscope the catheter is passed down to the bifurcation of the trachea and the supply of warmed ether vapour maintained by a bellows or preferably by an electric pump. The complexity of the apparatus and the skill required to pass the catheter have so far prevented this method being taken up in India. For thyroid and neck cases there is no better method than the rectal administration of a mixture of 75 per cent ether and 25 per cent olive oil (the percentage of ether should be less in young subjects), 1 ounce to each 20 pounds of body-weight up to a maximum of 8 ounces, preceded by morphine atropine injection. The patient is put to sleep in bed and is ready for operation in about 20 minutes; should the anæsthesia be light it can be deepened by a little open ether; in mouth operations the fact that the cough reflex is lost is a drawback,

necessitating careful swabbing to ensure that no blood enters the trachea.

During the last few years a great advance has been made in the technique of inhalation anaesthesia by the introduction of basal anaesthetics. These are substances that are administered to the patient before operation, depriving him of consciousness, so that he loses all sense of apprehension and knows nothing of the journey to the theatre or of the preparations for the operation. He wakes up some hours later, with the intervening period a complete blank and by that time post-operative shock and vomiting should have passed off. The value of all this in the case of nervous patients, of whom we have many in India, cannot be over-rated, and in addition these drugs have an even more important action in that they reduce the amount of the main anaesthetic agent that is needed to less than half, thus doing away with one of the chief objections to the open ether method of anaesthesia. These drugs fall into three chief groups:—

(a) *Paraldehyde*.—This is the writer's favourite for all abdominal work. A preliminary injection of atropine gr. 1/100 is given and, about three-quarters of an hour before operation, paraldehyde, 1 drachm per stone of weight up to a maximum of 10 drachms in 10 times its bulk of saline, is run into the rectum, which should be cleared by an enema 3 or 4 hours before. It is important that the paraldehyde be fresh, otherwise acetic acid may have been formed by decomposition, which will irritate the rectum and lead to its rejection. A dose of veronal overnight helps greatly. A deep sleep will be produced and only about 6 to 7 ounces of ether are needed for a cholecystectomy or gastro-enterostomy. Children take this drug very well. The only ill-effect is that patients, especially if alcoholic, may be boisterous and excited for some hours afterwards. The anaesthesia from the surgeon's point of view is perfect with excellent relaxation, and the method is of wide applicability.

(b) *Avertin (tribrom-methyl alcohol)* is also used by rectal injection, the dose being 0.1 gramme per kilogramme of body-weight, diluted in saline. Its effect is similar to that of paraldehyde, but its narcotic action is more profound and relaxation more perfect, there is a tendency to a fall of blood pressure and so the margin of safety is narrower. The amount of ether necessary after avertin is smaller than in the case of paraldehyde, about 4 ounces sufficing for most purposes and it must be admitted that the anaesthesia is more perfect, but against this must be set its high cost, about three to four rupees per dose (according to dosage) as against three annas per dose of paraldehyde.

(c) *The barbiturates* of which nembutal and pernocton are the most used. I have only experience of nembutal, which I frequently use in doses of $4\frac{1}{2}$ grains orally as a preliminary to

operations under local anaesthesia by regional or nerve block. Patients hardly notice the needle pricks and with this aid the scope for local anaesthesia in India is much enlarged, as by putting the patient to sleep it obviates the principal objection to these methods. It may be given intravenously or orally, the results with the former method being better, as the more exact dosage reduces the amount of the main anaesthetic necessary. When it is given orally the rate of absorption varies and therefore so does the time taken to put the patient to sleep. The sedative effect lasts 1 to 5 hours and there is complete amnesia for the whole period.

Sodium evipan is the latest addition to this series. It is given by intravenous injection, the dose being graduated according to the effects observed during injection of the first 4 c.cm. It gives complete analgesia commencing within a minute and lasting about 20 minutes. It is admirable for short operations not requiring perfect relaxation and we have found it useful for putting Kirschner wires through the tibia or os calcis, and in setting up fractures of the femur or tibia and fibula. By the time the patient comes round the limb is slung up in the skeleton splint with the extension in action, the absence of relaxation not being of much importance where skeletal traction is to be employed, though it renders the method unsuitable for putting up fractures in plaster-of-Paris, where the position must be perfect before the cast is applied.

Nitrous oxide and oxygen anaesthesia was developed during the war. It is of immense value in patients suffering from severe shock or acute sepsis, on account of the lack of toxic properties in the agents employed and the rapidity of elimination. For these reasons it is the anaesthetic of choice in many acute abdominal cases and in diabetics suffering from surgical complications, both classes of patient who are peculiarly susceptible to the poisonous action of ether and chloroform. It has serious drawbacks however, the heavy bulky plant, the necessity of an expert anaesthetist and the enormous cost of the nitrous oxide in this country. In abdominal surgery it is not satisfactory on account of the imperfect relaxation but this can be counteracted by the preliminary use of basal narcotics. My personal practice is to reserve it for use in diabetic cases and in acute abdominal cases that are bad risks.

Cost.—The comparative cost of the methods described above works out as follows at the ordinary Calcutta prices of the drugs used, though of course they would be cheaper in the case of hospitals that obtained them from the Medical Stores or through a 'home indent'.

1. Morphine, atropine, and ether
say 1 pound .. Rs. 3-8
2. Paraldehyde 1 ounce and
ether, say, 6 or 7 ounces Re. 1-11

THE CHOICE OF A GENERAL ANÆSTHETIC IN MAJOR OPERATIONS IN INDIA

By M. C. GANGULI, M.B.

Anæsthetist, Medical College Hospitals, Calcutta

Up to the beginning of the last decade the selection of an anæsthetic in India was a matter of 'Hobson's choice', because chloroform was practically the only anæsthetic used; the words chloroform and anæsthetic were almost synonyms, and the anæsthetist was often known as the 'chloroformist' by the profession as well as by the general public.

It would perhaps be out of place to give all the reasons why chloroform has maintained its popularity in this country; suffice it to say that the two main ones are the ease with which it can be administered and its cheapness. Furthermore, it has hitherto been the exception in this country for any thorough enquiry to be made by the authorities into a case of death during anæsthesia. The consequence has been that any person—qualified or not—has been able to style himself an anæsthetist and to administer chloroform; the amount of skill required for this is minimal, and the risk was entirely borne by the unfortunate patient.

Fortunately the times are changing for the better and, at least in the teaching hospitals in India, the number of which are gradually increasing, almost all recognized methods of anæsthesia are practised and the absolute supremacy of chloroform has been undermined.

The choice of anæsthetic has to be made from several points of view, those of the patient, of the surgeon and of the anæsthetist, independently and conjointly.

(Continued from previous page)

3. Avertin 7 c.cm. and ether
4 ounces Rs. 4-14
4. Nembutal $4\frac{1}{2}$ grs. and ether
6 ounces Re. 1-14

Spinal anæsthesia

As this forms the subject of another paper in this issue I do not propose to deal with it. Its utility in the surgery of the lower half of the body has long been recognized and for some time I have employed the method used at St. Mark's Hospital for rectal work. Half a c.cm. of 10 per cent stovaine in normal saline is injected with the patient sitting up until the anæsthesia begins to develop, when he lies down. The result is anæsthesia of the rectum, perineum and neighbouring parts without paralysis of the legs; the relaxation of the anal sphincter is perfect. The latest development is the use of perein for the production of anæsthesia extending high enough for abdominal work. I have been much impressed by the few cases I have so far seen and I foresee a great future for this method, especially when combined with a basal narcotic.

The patient wants an anæsthetic which will imperceptibly put him under its effects, and that rapidly, without the knowledge and terror of going under an anæsthetic. He must not have the slightest misgiving about the safety of the procedure, not only as regards his life, but also as regards the feeling of pain. In other words the patient should not have the least degree of psychic shock, and lastly he wants to be absolutely free from post-anæsthetic troubles.

The surgeon can only be at his best when there is complete relaxation of the field of operation and of the whole muscular system, when the heart is beating regularly, the blood is a bright red colour, and the anæsthetist quite free from anxiety.

The desire of the anæsthetist is not different from that of the patient and the surgeon, but in addition he wants the anæsthetic to be easy of administration.

Have we such an anæsthetic? Unfortunately to-day the answer is in the negative. We have no single anæsthetic which is ideal and will fully satisfy all, but with a proper combination of different anæsthetics, with a skilled administrator, and an appreciative and light-handed surgeon one can almost reach the ideal desired.

For many years morphine and scopolamine were the only drugs used to lull the patient's fears and abolish his excitability before the actual administration of an anæsthetic, and since the experiments of Crile showed that pre-medication by morphine prevents shock to an appreciable degree it has been used with much greater frequency. But the quest for a better pre-mediator went on as it was found that morphine and scopolamine did not sufficiently reduce the total amount of anæsthetic required during an operation, with its attendant risks. The results have been encouraging. To-day we have several pre-anæsthetics which also act as basal narcotics or sub-anæsthetics. They are so called because by their use the quantity of actual anæsthetic required to maintain anæsthesia can be reduced to an amazingly small amount.

Ether, avertin and paraldehyde by the rectal route in the proper dose, administered by the attending nurse in the ward, put the patient to sleep in his own bed and he does not know just what is going to happen. He is carried in his sleep to the operating theatre where the operation is performed in comfort, with very little inhalation anæsthesia or local infiltration. The patient is returned to his bed and wakes up from a fairly long sleep hardly believing that the whole thing is over. More recently we have still other basal narcotics wherewith to achieve the same end—the barbiturates, e.g., pernocton, amyral and nembutal. They may be used intravenously or by the mouth.

Regarding safety, it must be confessed that there is no anæsthetic or even sub-anæsthetic

which ensures cent per cent safety. Drugs introduced into the system by parenteral injection or by the mouth are uncontrollable, because a dose calculated to be appropriate for a certain patient may prove an over-dose and the excess can neither be withdrawn nor efficiently combated; furthermore, as the elimination of injected drugs is slow, troublesome or even fatal consequences may ensue. The idiosyncrasy to morphine is almost proverbial and the behaviour of scopolamine is wayward, as in some cases instead of the expected depression of the cerebrum it may actually excite it. The safe dose of the barbiturates has not yet been worked out to full satisfaction. The minimum effective dose should be given by the intravenous route. By the mouth or by the rectum they can also be given, but their action is delayed and the dose is difficult to regulate. They are very toxic—nembutal and pernocton being twice as toxic as the sodium amytal. The rectal injections also are not completely controllable, but they are partially controllable, as an excess can be withdrawn from the rectum unless some has escaped into the upper parts of the gut by retro-peristalsis. Avertin is perhaps more toxic than ether and ether more than paraldehyde, though at the same time their anæsthetic properties are in proportion to their toxicity.

The verdict against chloroform as the most dangerous drug has been passed by a consensus of opinion. Ether is decidedly safer and nitrous oxide with oxygen the safest, ethylene standing midway between the two.

Unfortunately with the great majority of anæsthetics post-anæsthetic complications cannot be completely avoided. With gas and oxygen, however, lung complications do not occur and vomiting is rarely seen. With ether and chloroform, vomiting and pulmonary complications are often distressing the latter trouble being more common with ether, but, with a progressive knowledge of better pre-operative preparation, improved methods of anæsthesia and pulmonary ventilation, the post-anæsthetic complications have been reduced to a minimum. By avoiding dehydration due to starvation and excessive purgation and by increasing the glycogen reserve with glucose and by alkalization, the acidosis is greatly lessened and the patient bears the post-operative period in much less discomfort. By attending to the infective foci in the mouth, by diminishing secretions with a preliminary injection of atropine, by warming the anæsthetic vapours, by avoiding all shock-producing factors, and by adequate ventilation of the lungs with inhalation of carbon dioxide and oxygen, during and after the operation, pulmonary congestion, post-operative atelectasis and pneumonia have become rare. The patient is also rapidly de-anæsthetized by increasing the pulmonary ventilation with carbon dioxide, and the drugs,

acting on the organs for a minimum period, hardly affect them adversely.

Complete relaxation of the field of operation and the whole muscular system is essential, not only for the surgeon to operate in comfort, but also for the prevention of shock and the success of the operation as a whole. Greatest relaxation is obtained by chloroform, less by ether and least by nitrous oxide and oxygen; but relaxation with chloroform is obtained at the sacrifice of safety, because, it has been calculated, the difference between the percentage of chloroform in the blood required to obtain complete narcosis with relaxation and the lethal dose is very small, and consequently, even with long experience, extreme vigilance is absolutely essential to prevent a catastrophe. With ether an adequate relaxation can always be attained with a fair margin of safety, and as the respiration and circulation are stimulated by it the colour of the blood is kept very satisfactory. Though gas and oxygen is the safest of them all the relaxation it gives is quite insufficient for most abdominal operations.

To get access to the organs during an operation the surgeon has often to compete with the muscles of the abdomen, and the struggle that ensues produces a degree of shock for which the safety of the gas can hardly compensate, and a 'safe' anæsthetic becomes dangerous, due to its inefficiency.

The anæsthetist can be free from anxiety only when he knows his work. He must be thoroughly familiar with the dangers, defects and the action of the agent he is using, the requirements of the operation, and with the peculiarities of the surgeon. To enable the anæsthetist to work at his ease the surgeon must not only know him, but also the limitations of the anæsthetics used. There must be a thorough understanding between the surgeon and the anæsthetist for a smooth-sailing operation. There are times when the 'surgeon has to unbend and the anæsthetist rise to the occasion'.

As regards easy administration of an anæsthetic it may be mentioned that the greater the skill the anæsthetist acquires the easier the administration becomes. Paradoxical though it may seem, usually the safer anæsthetics require greater skill than the less safe ones, and in this apparent ease in the administration of the latter lies one of their dangers, because, as I have already said, anyone feels himself competent to administer them.

It will appear now that we possess very satisfactory pre-anæsthetics and though the means to prevent post-anæsthetic complications have been greatly improved there is still room for advance. The two factors with which one is most concerned is the safety and efficiency of an anæsthetic. Our safest anæsthetic is not the most efficient nor is the most efficient the least

(Continued at foot of opposite page)

SPINAL ANALGESIA*

By J. C. DRUMMOND, M.Ch., M.B. (Liv.),

F.R.C.S. (Edin.)

CAPTAIN, I.M.S.

Junior Visiting Surgeon, Medical College Hospitals,
Calcutta

THE reduction in the mortality rate of extensive operative procedures which has followed upon recent anæsthetic developments has brought a realization that our two old stock anæsthetics, chloroform and ether, are greater tissue poisons than we had previously thought. Until research produces a more ideal inhalant they will still be necessary, but the present tendency is to restrict their use to a minimum,

(Continued from previous page)

safe. But it must be realized that though safety is our primary concern it is not the sole concern. The operation has to be done and that successfully. So one has to strike a middle course and select a combination of anæsthetics which will not be unpleasant to the patient, and at the same time ensure the maximum of efficiency with safety.

With an injection of morphine and hyoscine, or the administration of an actual basal narcotic—preferably rectal paraldehyde—the induction with ether with its smell and irritation is rarely unpleasant and often not objected to by the patient at all. Induction of anæsthesia with nitrous oxide and oxygen after pre-medication, and maintenance by it with additional ether, when required for satisfactory relaxation, is least disagreeable to the patient, safe in the extreme, and efficient to the maximum, with post-anæsthetic sequelæ reduced to the minimum. The difficulty with nitrous oxide in this country is its high price and that it requires a rather expensive machine and a skilled anæsthetist. So it is usually not available except for the lucky few and its place has to be taken by the less desirable ether in the large majority of cases; or some other method—local or spinal—has to be combined with basal narcosis.

The selection of an anæsthetic or combination of anæsthetics in patients of different age and physique, and in different pathological conditions, is a matter which requires careful consideration, but which it is not the purpose of this paper to discuss.

In conclusion, it may be stated that there is no single anæsthetic which will meet all requirements. To do the best for the patient an anæsthetist must be familiar with all the methods of administration, so that he may choose the right anæsthetics suitable to the particular case, and 'as an artist becomes skilful in mixing his colours, so must the anæsthetist become skilful in arranging his anæsthetic sequences'.

or, in certain cases, to dispense with them altogether. Among the newer methods which have come into use, intrathecal analgesia has made a reappearance in an entirely new guise, shorn of most of its previous disadvantages and with newly acquired merits.

HISTORICAL

The subject dates back to the work of Corning in 1888. The earlier results were, on the whole, disappointing. The drugs used were unsuitable, the diffusion and gravitation of solutions in the subarachnoid space were not properly understood, the technique imperfect and the wrong type of case was frequently selected for its application. A revival of popularity followed the introduction of stovaine, limited controllability having been attained by making the solution hyper-baric, i.e., heavier than cerebrospinal fluid, by the addition of glucose. This, however, never seriously competed with the older anæsthetics for routine use, and the majority of surgeons gave it up altogether.

In 1928 a tremendous impetus was given to the subject by the work of Dr. George P. Pitkin of New Jersey which resulted in the preparation known as spinocaine and the technique with which it is employed. In the December issue of the *American Journal of Surgery* for that year no fewer than fourteen articles appeared on the subject, and, for the first time, spinal analgesia began to be used on an extensive scale. The following year saw the introduction of a new drug, perein, chemically unrelated to the novocaine group and possessing characteristics especially suitable to intrathecal analgesia. This drug lends itself so well to surgery of the upper abdomen that many surgeons now use it as a routine in such operations.

ADVANTAGES OF SPINAL ANALGESIA

1. The absence of the secondary devitalizing effects of prolonged anæsthesia with ether or chloroform, leading to quicker post-operative recovery.
2. No post-anæsthetic strain trauma due to vomiting and coughing.
3. Rarity of pulmonary complications. This is specially valuable in India, where pulmonary complications are commoner than in Europe.
4. Food may be taken early, and will be digested and assimilated.
5. In some cases a patient may be permitted to suck toffee or drink an egg flip while the operation is actually in progress.
6. It is effective in strong subjects and in alcoholics. For patients who come into both these categories, it is perhaps the only satisfactory anæsthetic.
7. It provides incomparable muscular relaxation.
8. Better surgical exposure in abdominal operations is allowed. This is partly due to the

* From a paper read at a meeting of the Calcutta Branch of the British Medical Association, 10th November, 1933.

absolute relaxation and partly to the collapse of the intestines which is produced by paralysis of the inhibitory fibres of the sympathetic. This leads to less rough handling of the viscera or dragging on the mesentery and to more facile and quicker operative technique. It is possible to work through a smaller incision.

8. In out-stations, where no skilled anaesthetist is available, it facilitates the performance of operations which could not otherwise be safely undertaken. Needless to say, it is not advisable to dispense with the anaesthetist if one is available.

9. The apparatus is simple, portable and cheap.

10. Some patients prefer it.

It will now be convenient to deal briefly with the three drugs which have been chiefly used in the production of spinal analgesia—stovaine, novocaine and percaine.

STOVAINE

This is employed in 5 per cent or 10 per cent solution rendered hyper-baric by the addition of glucose. Half to 2 c.cm. are injected in the lumbar region with the patient in the sitting position, the solution descending to the lower part of the spinal canal by the action of gravity. The action is somewhat uncertain and analgesia above the umbilicus cannot be obtained by this method in safe dosage. The fall in blood pressure is severe, because of the toxic nature of the drug, the high concentration in which it is employed, and the absence of a viscid vehicle to slow down the rate of absorption and assist evenness of diffusion. Unpleasant sequelae frequently follow its use,—*e.g.*, severe headache, urinary incontinence or spasm of the vesical sphincter, paralysis of the sixth cranial nerve and even degenerative changes in the cord (Spielman). In the past it has been frequently used on patients suffering from shock or in too devitalized a condition to stand a general anaesthetic, in fact on the type of patient least suited to spinal analgesia. It is scarcely to be wondered at that it never came into universal use and that it is now practically obsolete.

Following the introduction of spinocaine, I applied stovaine to the Pitkin technique, in more dilute solution, rendered hypo-baric. Though satisfactory analgesia of the upper abdomen was obtained, many of the disadvantages of the drug were still present and I have never felt at ease while using it. In the past it has enabled me to operate where no skilled anaesthetist has been available, but I think that its use now is unjustifiable and that it should be relegated to the realm of the medical historian.

SPINOCAINE

The active principle is novocaine, the toxicity of which is not high. The objections to intrathecal novocaine that previously existed were

(1) the transitory nature of the analgesia, (2) the lack of control of the height and extent of the analgesia, and (3) the serious drop that occurs in the blood pressure. The formula and technique of using spinocaine was devised by Dr. Pitkin with the object of negating all these in the following manner:—

1. The transitory nature of the analgesia is corrected by addition of a viscid substance, gliadin, which delays absorption and prolongs the effect to about one and a half hours. It also assists to even out the diffusion and prevent toxic symptoms due to too rapid absorption of the novocaine.

2. Controllability is achieved by rendering the solution hypo-baric by the addition of alcohol so that it floats on the cerebrospinal fluid 'like an air bubble in a spirit level'. The injection is made in the upper lumbar region with the patient lying on his side, the head being lower than the spine. The attitude may be varied so that the part of the cord to be anaesthetized is uppermost and the height of the analgesia may be controlled by placing the patient in varying degrees of the Trendelenberg position.

3. The drop in blood pressure is controlled by the addition of strychnine to the solution and by the preliminary injection of ephedrine-adrenalin. The latter is given together with a local anaesthetic used to anaesthetize the site of the spinal injection.

The success of spinocaine may be gauged by the extent it has been used. Many surgeons in America employ it on every possible occasion, even for operations on the breast. Strauss, in his joint statistics of 83,698 cases, calculated a mortality of 0.016 per cent, or one death in every 5,978 cases. Carre and Borchard stated that they expected three immediate and three remote deaths in every 10,000 cases. It must be remembered, however, that these are the figures of experts; mishaps which occur in the hands of the occasional operator are a little apt not to be recorded.

In practice, though excellent results can be obtained with spinocaine, it is sometimes wayward in action and does not always behave like the bubble in the spirit level. The alcohol in the solution may mix with the cerebrospinal fluid, precipitating the heavier constituents to the action of gravity. Further, it is based on a normal specific gravity of the cerebrospinal fluid of 1007, but this is subject to fairly wide variations—between 1003 and 1010. Like stovaine, it is given in concentrated solution, and, in spite of the viscid substance added, ocular palsies and other unpleasant symptoms have been observed. It must be admitted that in spite of careful technique small quantities of spinal analgesic solutions are liable to reach a higher level than intended, and it follows that no concentrated solution can be really safe.

I still use spinocaine for inguinal herniotomy, where small dosage suffices and absolute relaxation and prolonged action are not required, but I have given it up in favour of percaine for high abdominal analgesia.

PERCAINE

This is a quinine derivative having no chemical relationship to any other local anæsthetic. It is used in extreme dilution, being weight for weight easily the most powerful local anæsthetic known. In the spinal theca 7.5 milligrammes of percaine will produce an analgesia more intense and considerably more prolonged than 150 milligrammes of novocaine. The dilution of effective solutions is so extreme that the weight of the drug adds practically nothing to the specific gravity of the solvent and makes it unnecessary to resort to the addition of alcohol to produce a hypo-baric solution. When sufficiently diluted it exerts a selective action on the anterior roots of the dorsal nerves, giving the absolute relaxation of the muscles of the abdominal wall which is so characteristic of the drug, while having no appreciable effect on the phrenics or vital centres of the medulla, in normal dosage. No cases of ocular palsies have been recorded. In dilutions of 1 in 1,500, or greater, it can be injected in comparatively large bulk (20 c.cms.), leading to more uniform certainty of action. Post-anæsthetic headache is rare and the fall in blood pressure is relatively small and readily controlled with ephedrine. No cases of vesical incontinence or irritability have been recorded. Constipation for two or three days has been noticed in cases in which the mesentery has been pulled on, but this is probably true with all anæsthetics. There is, however, one disadvantage. As the maximum effect is on the anterior roots of the dorsal nerves some or all of the intercostal muscles are put out of action. If analgesia is obtained to a high level, respiration may be dependent on the phrenics. In practice, this does not matter if oxygen be available.

PSYCHIC CONSIDERATIONS

Though spinal anæsthesia may be safe and ideal from the point of view of the surgeon, it may not be satisfactory to a nervous and highly-strung patient. The avoidance of psychic shock is important. If the patient is at all apprehensive, morphia may be given an hour before operation and the ears plugged with cotton-wool. The combination of avertin and percaine has been advocated, but the use of any drug which masks the action of the spinal analgesic is undesirable. I find that a minimum dosage of percaine combined with open ether is very satisfactory in nervous cases. The ether is not administered until after the action of the percaine has been ascertained, and it is surprising how little need be given.

BASAL ANÆSTHESIA*

By PROFULLA KUMAR MUKHERJEE, M.B.

*Anæsthetist to the Professor of Surgery,
Medical College Hospitals, Calcutta*

A BASAL anæsthetic is one which acts as a base for the administration of some other form of anæsthesia or analgesia, thereby reducing the amount of anæsthetizing agent required and minimizing the insult to the tissues caused by this agent. It is needless to point out the advantages to be gained in prolonged and difficult surgical operations by restricting to a minimum the amount of chloroform or ether used. The striking decrease which has been accomplished in the mortality rates of severe surgical procedures by the employment of modern anæsthetic methods is now well known.

Even if research were to produce a non-toxic inhalation anæsthetic, free from the unpleasant features of chloroform and ether, basal anæsthesia would still retain a position amongst the agents at our disposal by reason of an inherent virtue not possessed to any appreciable extent by any other method. I refer to the avoidance of psychic trauma, or, as Crile puts it, 'anoci-association'. By its use a nervous patient may swallow a tablet or have an injection in the ward and pass into a deep sleep before he enters the operating theatre. When he wakes up again, he is back in the ward with his operation over. He is spared the apprehensive journey from the ward to the theatre, the suspense of waiting for his turn and the sight of

(Continued from previous column)

SELECTION OF CASE

A few years ago the attitude frequently taken towards spinal analgesia was 'this patient won't stand a general anæsthetic; let's give him a spinal'. It is now realized that the patient who is shocked or devitalized by some toxic condition or wasting disease is not a suitable subject. Regional analgesia offers a safer alternative in these cases. There are some who go so far as to say that spinal analgesia should never be used on a bad risk case, but there are some bad risks in which absolute relaxation is essential to the safe conduct of the operation, intestinal obstruction for example. The recent acute abdomen in a fairly robust individual is not considered to be a bad risk. A change has also taken place in the type of operation in which spinal analgesia is most commonly employed. Previously used for operations on the pelvis and lower limbs, it has become mainly an abdominal anæsthetic, particularly for extensive resections and operations where wide exposure is required.

* Paper read at a Clinical Meeting of the British Medical Association, Calcutta Branch, on the 10th November, 1933.

white-robed figures and instrument cabinets. Post-operative neuroses are avoided, the mental outlook of the patient less disturbed and convalescence accelerated.

Drugs employed

The chemist is producing new drugs for basal anaesthesia faster than the clinician can test them. It can safely be predicted that still more perfect drugs will be available in a few years time. Those now in most common use are :—

- (1) Derivatives of barbituric acid.
- (2) Avertin.
- (3) Paraldehyde.

1. Since the introduction of veronal thirty years ago many derivatives of barbituric acid have been produced. They may be roughly divided into two groups—those that are relatively non-toxic, are slow in absorption and have prolonged action, and those that are more toxic, are rapidly absorbed and have a shorter action. The ones that have given satisfactory results are nembutal, evipan sodium, and pernocton, and amongst these nembutal in my hands proved to be of special advantage.

Nembutal.—Though this can either be given intravenously or by the mouth, oral administration has been the method of choice and in Indian patients doses of $4\frac{1}{2}$ grains for males and 3 grains for females have been used. Sleep follows in about half an hour. Corneal reflex is maintained, as is the cough reflex. The additional anaesthetic used in this series has usually been 1 per cent novocaine solution either as an infiltration or as a nerve block and this procedure has invariably proved of extreme advantage in cases of operations on the jaw inasmuch as the patient has been quiet, subconscious and unconcerned, yet whatever trickled into the throat has been thrown out by the patient. No late toxic effects have been noticed.

Evipan sodium.—The solution is freshly made in 10 c.cm. of triple distilled water which is supplied by the maker in a separate ampoule and 4 c.cm. of the mixture is injected intravenously at the rate of 0.5 c.cm. per half a minute and the muscular relaxation, as evidenced from observation of the masseter, is used as the guide to subsequent dosage. The injection may, if necessary, be continued up to a maximum of 10 c.cm. until the desired depth of anaesthesia is obtained. The anaesthesia it yields is somewhat transient and variable, the relaxation is imperfect, and thus its value is confined to short operations where relaxation is not required. Alcoholics get boisterous; some are susceptible and the respiration is often depressed, and in one case it went down to three.

Pernocton.—It is obtained in ampoules. The dose is calculated from body-weight—0.5 c.cm. for every stone of body-weight with 0.5 c.cm. added to the total; this is injected

into the vein at the rate of 0.25 c.cm. per quarter minute.

The drug is inefficacious on alcoholics and some non-alcoholics also remain wide awake. The quantity of inhalation anaesthetic required is not appreciably diminished. Post-operative morphia is required in every case.

2. *Avertin.*—Avertin is tri-brom-methyl alcohol and is available both in crystals and fluid form. The latter is more convenient to measure, but slightly more expensive. It is a somewhat unstable drug and must be tested for decomposition before use. This is done by the addition of a few drops of Congo red solution, 1 in 1,000, before administration. If the indicator does not change its colour, the solution is safe for use. In actual practice, no trouble has been experienced by decomposition of the solution.

It is administered by the rectal route, the dose being calculated by body-weight, 0.1 c.cm. of fluid avertin per kilogramme of body-weight. The avertin is diluted, or rather emulsified, in forty times its bulk of distilled water roughly at body temperature and slowly instilled into the rectum. A simultaneous injection of hyoscine compound is given. The patient falls into a deep sleep a few minutes after the completion of the rectal instillation and is ready for removal to the theatre. During this stage it is advisable not to have the patients disturbed, as for example, by being examined by students. Open ether may be administered without risk of waking the patient. His heart is not weakened by his fighting and struggling in the second stage, and muscular relaxation is obtained with a comparatively trifling dose of inhalation anaesthetic. The slow, easy, natural type of respiration is reassuring both to surgeon and anaesthetist. The patient returns to the ward still asleep, unlikely to be troubled with vomiting and the trauma of straining after operation, or to contract pulmonary or gastro-intestinal complications.

Avertin has been used in 65 selected cases of major operations with satisfaction to the surgeon, the patient and myself. Compared with other basal anaesthetics, its main disadvantage lies in its cost. As already indicated, its instability has not been found to be a disadvantage in actual practice. It is fairly sure in action, sleep is early and deep, and it contributes to relaxation to a greater extent than any other basal narcotic, therefore less inhalation is required to complete the anaesthesia.

In calculating the dose it has been found that 5 c.cm. of avertin is sufficient; weight due to superfluous fat should be neglected in estimating the dose. With larger doses slight cyanosis often prevails. One disadvantage however is that the blood pressure falls 10 to 20 mm. of Hg. within the first fifteen to thirty minutes.

The drug has been used in conjunction with ether in most cases, with novocaine infiltration in three cases of tumour of the thyroid, two

cases of cancer of the breast (total removal) and one case of tumour of the jaw, and with spinoecaine in three cases of acute abdomen. It is a bad risk with spinoecaine as both of these drugs reduce the blood pressure. This may, however, be counteracted by the combined use of ephedrin and adrenalin.

Of the 53 cases done with ether, slight congestion of the lungs at the base developed in four and there was troublesome vomiting in three gastro-jejunostomy cases.

In one case of cancer of the breast done with avertin and ether the patient died of sudden heart failure 10 days after operation when the stitches had been removed from a perfectly clean healing wound. After death the family doctor gave a history of the patient having had heart attacks. The blood pressure before operation was 120 systolic and 70 diastolic. Autopsy was not allowed.

In one case of cancer of the breast done with avertin and novocaine infiltration the patient died five days after operation with symptoms of ileus starting from the second day after operation. The patient was aged 60 and weighed 22 stone; the systolic blood pressure was 130, diastolic—70. Only 5 c.cm. of avertin and a 0.5 per cent solution of novocaine were used.

No other trouble was encountered in the whole series.

3. *Paraldehyde*.—The drug must be chemically pure, otherwise it gives rise to an irritative colitis.

The dose is calculated from the body-weight, one drachm for each stone, the limit being fixed at one ounce. This is diluted twelve times in normal saline. Seven and a half grains of veronal are given overnight; atropin 1/100th grain is injected and then the solution is slowly instilled per rectum. The patient falls asleep in about half an hour. In a series of one hundred cases in which this form of anæsthesia was used, congestion at the base of the lungs appeared in only two and troublesome post-operative vomiting was not noticed in any. A comparison with avertin is detailed below and will amply justify its use as the basal anæsthetic of choice.

Paraldehyde

Avertin

Cheap	More costly.
Stable	Not so stable.
Larger in quantity and requires care and preparation to make the patient retain it.	Small in quantity and easily retained.
Sleep comes in half an hour or more and is light.	Sleep is early and deep.
Very little muscular relaxation.	Helps materially to muscular relaxation.
Quantity of additional anæsthetic required is larger.	Quantity of additional anæsthetic required is very small.

ETHYL CHLORIDE FOR SHORT ANÆSTHESIA

By A. GREVILLE YOUNG, L.R.C.P., L.R.C.S. (Edin.),
D.T.M. (Cal.)

Medical Officer In-Charge, Church of Scotland Mission Hospital, Jalna, Deccan

It appears that in many of the smaller hospitals in India full chloroform anæsthesia is given for minor operations. This is not necessary and I would like to suggest that the following method be tried more frequently.

Open ethyl chloride

Ethyl chloride, of course, is given easily and efficiently by means of an inhaler, but many hospitals do not possess such an inhaler. Thus we have come to use ethyl chloride on an open mask. For teeth extractions a gag is first inserted. Then a Schimmelbusch's mask with four layers of gauze is applied to the face. Round the mask a towel is wrapped in such a way as to leave only a small portion of the gauze visible as is done when giving ether. Ethyl chloride is sprayed for a few seconds on the gauze and the patient is asked to breathe deeply. The area sprayed is then covered for a few seconds by the anæsthetist's free hand or by a corner of the towel. On removing the hand more ethyl chloride is sprayed and again covered. This is repeated three or four times. If there is any cyanosis the mask is removed momentarily to allow the patient to take a breath of ordinary air. The patient is usually 'under' in one or two minutes, a fact which is easily tested by lifting one of the patient's hands; if it falls limply then the anæsthesia is complete and the operation is at once performed. By further spraying, anæsthesia may be considerably prolonged, but one is not quite sure whether this is a safe procedure. It is probably better to change over to ether or chloroform. Since trying this during the last eight months on some hundred cases we have not observed

(Continued from previous column)

Often fails in alcoholics and in those addicted to drugs, making them boisterous and talkative.	Sure in action.
Requires no preliminary narcotic.	Requires a preliminary narcotic.
No contra-indications	Contra-indicated in cardiovascular and hepatic disorders.
While coming round the patient is sometimes boisterous requiring morphia.	While coming round the patient is quiet.

In conclusion I must thank Lieut.-Colonel W. L. Harnett, Professor of Surgery and First Surgeon, Medical College Hospitals, Calcutta, for kindly affording all facilities, and for help and guidance in carrying them out on the cases in his clinic.

any untoward symptoms. Occasionally we have had difficulty in getting big men, or heavy drinkers under properly and in these cases we have changed over to chloroform. It is to be noted that the anaesthesia in such cases has been quicker than with chloroform alone. Incidentally, it may be mentioned here that the mixture used by us with great success is chloroform 9 parts, and alcohol 1 part. The advantage of these short anaesthetics is that no

preparation is required. The patient rarely vomits and is able to walk home a few minutes after the operation. It saves considerable time too if there is only one operating table available. Ethyl chloride is obtainable almost anywhere. We have found the cheap variety (Schering), about Re. 1-2 for 100 grammes, quite efficient. Each tube lasts for five or even six patients, and so the cost per head is less than 4 annas.

Medical News

CONFERENCE OF THE INTERNATIONAL UNION AGAINST TUBERCULOSIS

THE annual meeting of the Council of the International Union against Tuberculosis, whose Chairman is Professor Nolen (Netherlands), was held in Paris, on Saturday, 22nd July; delegates from fourteen countries attended this meeting. At 10 A.M. an administrative session took place at the headquarters of the Union, 66 Boulevard St. Michel, Paris. It was decided that the Conference of the International Union would be held in Warsaw on the 4th, 5th and 6th September, 1934, and that the three following subjects, selected from a list of questions submitted by the various countries belonging to the Union, would be entered on the agenda:

Biological subject: *Biological variations of the tubercle virus*, opening report by Professor Karwacki (Poland);

Clinical subject: *The various forms of osteo-articular tuberculosis and their treatment*, opening report by Professor Putti (Italy);

Social subject: *The utilization of dispensaries for the treatment of tuberculous patients*, opening report by Professor Leon Bernard (France).

Mr. John A. Kingsbury of the United States will give a lecture on 'Methods in further control of tuberculosis—Report upon an experiment in a rural area characterized by a low tuberculosis rate'. According to the plan followed at Oslo and at The Hague, ten speakers selected from different countries will be designated to open the discussion on each of the three main subjects.

The scientific session which took place at 3 P.M. was devoted to a report by Dr. Saenz on 'Tuberculosis bacillæmia'. The report was followed by a discussion in which Professor Leon Bernard, Secretary General of the Union, Professor Valtis (Greece), Professor Bezancon (Paris), Professor Yevrem Nedelkovitch (Yugoslavia) and others took part.

BATH

THE following news item has been received from Bath:—

A good many prominent Indians have visited Bath, the historic English health resort, this summer. Sir Prabhashanker D. Pattani when in England never fails to take a course of the Bath waters; an Indian doctor from Lucknow recently spent a short time at Bath studying the medical aspects of the Bath treatment for rheumatic diseases and the other conditions treated by the hot springs, and now Sir Hari Singh Gour is taking the cure.

MEDICAL AND SANITARY REPORTS FROM BRITISH COLONIES, PROTECTORATES AND DEPENDENCIES FOR THE YEAR 1931

A WEALTH of valuable information about health conditions in the individual colonies within the British

Empire may be found in the annual medical and sanitary reports issued by the various colonial Governments, but very few libraries in Great Britain or the Dominions and colonies have complete files of these publications so that the information they contain is not easy of access. Some kind of authoritative summary of these periodic medical reports has therefore long been needed and the Bureau of Hygiene and Tropical Diseases has recently taken over the responsibility of preparing such summaries and issuing them as special supplements to its *Tropical Diseases Bulletin*. So far two such annual supplements dealing with the reports for the years 1929 and 1930 have appeared. A third supplement to the *Tropical Diseases Bulletin* for October 1933 has just been published summarizing the 'Medical and Sanitary Reports from British Colonies, Protectorates and Dependencies for the Year 1931'. It contains detailed summaries written by Dr. H. Harold Scott, the Assistant Director of the Bureau, of reports from forty-nine colonies, mostly tropical or sub-tropical, and follows a general arrangement, giving for each country the year's record of vital statistics, maternity and child-welfare work, school hygiene, general sanitation, housing and town planning, etc., followed by particulars of the incidence of diseases, such as malaria, enteric fever, leprosy, yellow fever, trypanosomiasis, yaws and syphilis, and the measures taken locally to combat them. Information is also given about special health campaigns and investigations carried out in the various government laboratories or in the field into problems associated with diseases met with in the particular colony.

Thus the compilation provides a means for analysing the various factors that affect the physical well-being of European and native communities throughout the scattered colonial Empire, and records the organized efforts of the various administrations to improve the health conditions in their own localities. Its primary objective is to keep medical and research officers and administrative officers in any one region informed of work done in other parts of the Empire, but the information it contains should also prove useful for those visiting the colonies and dependencies on a pleasure trip, or those who are intending to reside and take up work there, in that they may see what are the prevalent diseases they may meet with and take precautions against, and the present state of health of the countries in which they propose to sojourn.

The supplement should be of value also to those who, though themselves living in England or other temperate climates, do business in the colonies, more particularly insurance offices, actuaries, etc. For the more ready conveyance of information of a kind likely to be required by this latter class of reader a table has been added, as was asked in a review of a previous publication of these summaries, giving in more succinct form the vital statistics and other cognate data relating to the various colonies. The supplement is published at five shillings.

ALL-INDIA MEDICAL LICENTIATES' ASSOCIATION

TWENTY-SIXTH ANNUAL CONFERENCE, BOMBAY SESSION
Christmas Week, 1933

The Secretary of the Scientific Committee appeals to all the members of the profession to send their contributions on any medical or allied subjects for the scientific section of the Conference, wherein such papers will be read and discussed under the presidency of specialists in each line.

All correspondence should please be addressed to Dr. U. A. Rao, Secretary, Scientific Committee, Reception Committee Offices, 94, Girgaum Road, Bombay 4.

The Secretary, Exhibition Committee, informs the various manufacturers and their representatives that the Eleventh Exhibition of Medical, Surgical and Sanitary goods will be held during the Conference session, under the auspices of the Association.

TENTH ALL-INDIA MEDICAL CONFERENCE, 1933

The Tenth All-India Medical Conference will be held in Bombay in Christmas Week of 1933.

Members of the medical profession are requested to attend the Conference, and to make it a success by personal attendance and reading papers of medical interest. As it is not possible to send invitations to individuals, this general invitation should be taken as a personal one.

Further information can be obtained from Dr. D. D. Sathye, General Secretary, 12, Girgaum Road, Bombay 4.

FIFTY YEARS AGO

(From the *Indian Medical Gazette*, December, 1883,
Vol. XVIII, pp. 344, 345 and 359)

THE NUDDEA FEVER

It has become a settled conviction, both in and out of the profession, that it is a disease of places, of soil; and the idea of communicability from man to man, or of portability from place to place, is not usually associated with it. The contingency of 'catching' malarious fever otherwise than by visiting or inhabiting the place where its cause, whatever that may be, abides does not enter men's minds, and the surest way of avoiding or escaping it is considered to be quitting its sphere of prevalence.

Within the last few years a new outbreak of this kind has made its appearance in the districts of Jessore and Nuddea, and caused great suffering and mortality. The Government of Bengal appointed a mixed commission composed of a medical man, a civilian, and an engineer, all officers of standing and ability, to investigate this outbreak. Their attention was specially directed to the testing, by careful observation and inquiry on the spot, of two theories which have been put forward to account for these epidemics. Both these theories attribute the intensification of the fever to obstructed drainage but they differ regarding the cause of obstruction. One view is that originally propounded by the late Rajah Degumber Mitter, an intelligent and observant Bengali zemindar. He held and endeavoured repeatedly to prove by argument and illustration that the obstruction of the drainage of the country was due to the construction of roads, embankments and railways without sufficient waterway. He adduced numerous instances which seemed to establish the truth of his contention, but his facts were all one-sided, and he failed to adduce or explain negative evidence of obstruction without fever or fever without obstruction. Moreover his theory, if true, would fail to explain the progressive character of the epidemics. The other view is to our mind more plausible and probable, namely, that the obstruction is caused by

those changes of level and natural drainage which are constantly occurring in deltas; rivers getting silted up and the water having gradually to find its way through new courses; more or less logging of soil taking place during the process of change. The conclusion arrived at by the commission is that neither one theory nor the other is adequate to account for the facts.

Dr. Lidderdale, the medical member of the commission, speculates that the ordinary fever germ acquires under certain circumstances virulent properties, and that it is capable of perpetuating its virulence by being introduced into fresh fields and pastures new through the instrumentality of man, and subsequently flourishing in a suitable and congenial nidus. The doctrine that the virulence of disease germs varies and that the variation depends on the circumstances of their development, growth, nutrition and life, has much to commend it to provisional acceptance, but it must be borne in mind that the speculation is entirely hypothetical, and will remain so until by the microscope or chemical analysis the germ has been isolated and its qualities determined.

INOCULABILITY OF LEPROSY IN ANIMALS

Dr. Otto Damsch has made a number of experiments on the inoculation of leprosy material in animals. The results seem to show positively that leprosy can be communicated to animals. Portions of leprosy tissue may remain for months in the animal body without the nuclei of the cells or the bacilli contained in them losing their power of absorbing colouring matter and becoming stained and the bacilli may not only remain intact for as much as four to seven months in the bodies of cats or rabbits, but they may actually multiply. His experiments show further that, where the bacilli penetrate, processes occur which are analogous to the leprosy processes in man, not only histologically but also in their progressive character and in their tendency to infect neighbouring tissues.

Current Topics

A Report on the Clinical Value of 'Evipan'

By THE ANÆSTHETICS COMMITTEE,
MEDICAL RESEARCH COUNCIL

(Abstracted from the *British Medical Journal*, 8th July, 1933, p. 63)

ENCOURAGING accounts of the action of yet another barbiturate anæsthetic, 'evipan', which came from German surgeons and anæsthetists, seemed to the Anæsthetics Committee to warrant a thorough clinical trial. Twenty-five thousand cases are reported from that country with one death attributed to 'evipan'. Accordingly, the offer of Bayer Products, Ltd., was gladly accepted and supplies of the new drug were put at the disposal of the Committee. Evipan sodium is the sodium salt of *n*-methyl-C-C-cyclo-hexanyl-methyl barbituric acid, and dissolved freely in water, but the solution is stable only for an hour or two.

TECHNIQUE AND DOSAGE

The evipan is supplied in powder form in ampoules to which the distilled water supplied in another ampoule is added. By aspirating and reinjecting once or twice a solution is obtained which passes easily through the ordinary hypodermic needle. This is inserted into a suitable vein of the arm with due antiseptic precautions. It is advisable to have the arm held steadily by a second person because of the twitching of muscles which often comes on early after injection has begun. The solution is run in at the rate of 1 c.cm. in fifteen seconds. Dosage is determined by the characteristics

of the patient and the results noticed. Acting on a definite scale arranged according to body-weight does not give satisfactory results. An average amount to produce unconsciousness is about 3 c.cm. A good plan, recommended by Lauber of Königsberg, who has had a big experience, is to make the patient count. When the counting ceases through sleep the amount that has been injected is noted, and the same amount is further added for a short operation, and twice as much for a long one. In elderly and feeble people, and those who have gone to sleep exceptionally quickly, only half the amount which produced sleep is added. Most patients are asleep in about one minute. There is often some twitching or jactitation, but often complete relaxation of the muscles of tongue and jaw occurs early, and care is needed to preserve a patent airway. Generally speaking, 10 c.cm. is regarded as the maximum dose. When it is desired to complete a longish operation under evipan only, the needle must be left *in situ* and a further injection made when the anæsthetic effect of the first is obviously wearing off. Used in this way as much as 20 c.cm. has been injected. There is, however, a fluctuation in the anæsthesia, and we do not see evidence of any advantage in the use of evipan for other than short operations—that is, of twenty minutes or so at the outside.

SYMPTOMS PRODUCED

A deep yawn just before the disappearance of consciousness is a common symptom. The great majority of patients fall asleep perfectly quietly. Twitching of face muscles is common, and there is sometimes jactitation of limbs. In one instance tonic contraction of many muscles and brief stoppage of respiratory movements were observed. The degree of muscular relaxation varies, but is rarely extreme or sufficient for an abdominal operation. The pupil is usually moderately dilated but active to light. In the early stages it is sometimes widely dilated. The conjunctival and, generally, the corneal reflexes have disappeared at the moment of fullest effect. Even then reflex movement at the start of operation has been seen many times. The eyelids are sometimes widely separated. The effects on blood pressure are slight. There is commonly a fall of about 20 to 30 mm. Hg., which is quickly recovered from. Respiration is often somewhat slowed, but there has been seen no serious depression except in one instance when, unknown to the anæsthetist, the patient, an elderly woman, had received a full dose of morphine and hyoscine before the evipan. The combined result was respiratory stoppage requiring, and removed by, artificial respiration and CO₂ with oxygen. It is inadvisable to give any sedative before evipan. No special preparation is needed, but it is of course desirable to have the stomach empty. Subjective symptoms as described by reliable patients are a feeling of quickly increasing lassitude which cannot be overcome and loss of consciousness in a few seconds. Experience shows, nevertheless, that it is best to wait two minutes after completing the injection before beginning to operate. The length of time of unconsciousness is usually about ten to twenty minutes after an average dose. After this time the patient can talk but is sleepy, and will drop off again if left quiet. When he finally wakes he remembers nothing after the first prick of the needle. As in the case of other anæsthetics there is considerable difference in the reaction of different persons to evipan, and the exact behaviour cannot be foretold. The patient may go to sleep with no apparent difficulty and the usual signs of anæsthesia be present, and yet there may be movement on incision, to an extent demanding a supplementary anæsthetic. On the other hand, it often happens that merely 3 c.cm. give a perfectly satisfactory, though of course only a short, anæsthesia. Our experience does not corroborate the statement of Ernst that one can reckon almost always on half an hour's good anæsthesia. We are led to believe that in Germany the surgeon is satisfied with a narcosis which is not regarded as enough by most operators in this country. Certainly the German

reports describe a more constant and sufficient anæsthesia than has been obtained here by the same dosage and technique.

CONCLUSIONS

It is obvious from what has been stated that evipan is not to be regarded as a basal narcotic in the sense that, for example, nembutal and avertin are. Its action is so evanescent that it cannot be employed, as are these drugs, for procuring a longish period of quiet or of unconsciousness before the administration of the anæsthetic proper, nor can it be used, as are the basal narcotics, to put the patient to sleep in his bed in order to avoid all knowledge of transference to the operating theatre. If it is used before another anæsthetic this must follow closely on the administration of the evipan, and as a preliminary, therefore, it is to be classed with nitrous oxide and ethyl chloride rather than with the basal narcotics. For those who like intravenous methods it is certainly an admirable means of inducing anæsthesia, all opinion agreeing as to the rapidity and pleasantness with which the patient becomes unconscious. Excitement or restlessness during induction have been seen only in unusually emotional subjects. After-effects also are of rare occurrence. It can be relied on for an excellent anæsthesia in minor surgery—that is, for short operations when the possibility of slight reflex movement is not a matter of great concern. It is true that often the anæsthesia is profound, and that by repeating the injection it can be prolonged; but it is not obvious that this is a better procedure than usual methods, such as gas and oxygen, for example. The recovery free from after-effects and the quiet induction make evipan a valuable agent in the case of persons gravely ill, for whom a short anæsthesia is desired for any reason. There are many such instances, when it would probably be preferable even to nitrous oxide. Two examples of this kind may be quoted from our series.

A man, aged 62, suffering from aortic regurgitation and arteriosclerosis, had amputation of the great toe for gangrene. He received 6 c.cm. evipan. Sleep was induced in half a minute. The operation took ten minutes, during which time the anæsthesia was all that could be desired: After twenty minutes he woke up yawning and was talking a minute later. Half an hour later he fell asleep and slept for six hours.

The other example was a man of 36 years, extremely ill with empyema after pneumonia. He was regarded as unfit for a general anæsthetic. Nevertheless, it was decided to use evipan, of which 10 c.cm. were injected. Anæsthesia was good, and the operation, rib-resection, was completed without anxiety. The patient was fully awake after three-quarters of an hour, and suffered no after-effects.

A few trials have been made of the efficacy of evipan by the mouth. It is described as proving less efficient thus given, than nembutal in the same circumstances. Nevertheless, two or three of the tablets in which it is provided for oral administration are a useful hypnotic, generally causing sleep in a short space of time. It is a useful agent with which to break a habit of sleeplessness.

Cystitis and Bladder Antiseptics

By JOHN MABERLY, L.R.C.P. (Lond.), M.R.C.S. (Eng.)

(From the *Medical Press and Circular*, New Series, Vol. CXXXVI, No. 4919, 16th August, 1933, p. 151)

In the bulk of cases of cystitis some bacterial infection is present. Leaving out bilharzia, which is treated specifically by tartar emetic, two groups of organisms are found in the urine. Firstly, the Gram-positive pyogenic organisms, staphylococci and streptococci, which are found almost exclusively in alkaline urine, and are capable, especially the staphylococci, of breaking up urea and giving rise to ammoniacal urine; and, secondly, *B. coli* or, more rarely, gonococci, typhoid, or tubercle bacilli, all of which prefer, and are usually

found in, acid urine. The subject of cystitis and infected urines naturally falls into two divisions, and is most conveniently discussed under the headings of (1) alkaline urines; and (2) acid urines.

(1) ALKALINE URINES

The cause of cystitis with an alkaline urine is some factor producing lowered resistance, such as chill, injury, calculus, enlarged prostate, stricture, residual urine, followed by infection with staphylococci or streptococci, introduced from some focus within the system, or from without via the urethra, in catheterization, for instance. The chief symptoms are frequent micturition, pain about the region of the bladder, urine cloudy with mucus, and usually pus, ammoniacal or offensive to the smell and alkaline in reaction. For practical purposes the presence of Gram-positive pyogenic bacteria may be inferred from the character of the urine.

Treatment.—Normal urine being acid in reaction, our endeavours must be directed towards reducing the urine to that condition, and if by medical means we can accomplish this, we shall at the same time cure the bacterial infection, seeing that the bacteria involved can only flourish in an alkaline medium.

Several drugs have from time to time been introduced to the medical profession as bladder antiseptics. Boracic acid is, I submit, the most reliable drug in cystitis with alkaline urine, and staphylococci or streptococci infection. It is also a healing drug in the simpler forms of cystitis. The first reference to its oral administration in English medical literature appears to be a letter by Dr. G. V. Percy, medical officer to the French Hospital in London, in *The Lancet* of 19th July, 1884. The following extract will convey the purport of that communication: 'The patient on whom I first tried it was suffering from a bad stricture of the urethra and perineal abscess. His urine on admission was strongly ammoniacal with flakes of mucus. Boracic acid was administered in 10-grain doses every three hours a few days after admission. In about twenty-four hours the urine changed in reaction, and when passing through the fistula—recently formed—did not scald nearly so much. Although the boracic acid was continued for a fortnight, no harm resulted from its continuous administration. The urine passed was kept in a vessel for several days without its undergoing decomposition; it also kept its acid reaction'. The second case was 'an old woman who had suffered from cystitis of doubtful origin for seven months previous to her admission. Urine was passed every quarter of an hour day and night when she came in. There was much irritation of the thighs, and much scalding on micturition. After trying several remedies with slight success, and the urine being distinctly alkaline and fetid, the boracic acid in 10-grain doses twice a day was ordered. As in the previous case, the reaction of the urine changed after the first day of taking the mixture, and has continued acid since. Her symptoms were greatly relieved'. In both cases an alkaline, ammoniacal and septic type of urine was converted in a few hours into an acid one by the administration of boracic acid.

Some unfavourable results reported in the medical journals as having followed excessive and poisonous doses of the drug appear to have alarmed the profession, and stood in the way of its general adoption as a urinary and bladder antiseptic. Scattered through medical literature, however, we find occasional references to the use of boracic acid in diseased conditions of the urine and bladder. For instance, in Freyer's work on stricture of the urethra and hypertrophy of the prostate (1902), in discussing the treatment of cystitis with enlarged prostate, he says: 'When the urine has a tendency to become cloudy and gives off a fishy, offensive odour, the best drug to administer is boracic acid'. In most textbooks, however, the use of the drug as a bladder and urinary antiseptic, when given by the mouth, is not mentioned. For some obscure reason hexamin (urotropin) in conjunction with acid sodium phosphate has come into general vogue among

British practitioners, and has entirely superseded the older drug.

The laboratory experiments carried out on behalf of the Science Committee of the British Medical Association by Dr. Anson Jordan on urinary antiseptics (*B. M. J.*, 13th September, 1913), although they do not entirely coincide with clinical experience, throw a useful light on the subject. The most important conclusions arrived at were: First, that the antiseptic power of urotropin is entirely dependent on its disintegration and the formation of formaldehyde. Second, in neutral solutions this disintegration takes place only to a very small and practically negligible amount, and in alkaline solution not at all. Third, in acid solutions the percentage of urotropin which breaks up increases considerably in a degree related to the acidity.

The object therefore in giving urotropin as a urinary antiseptic is to exhibit formaldehyde, and this action is entirely dependent on the question whether in clinical work it is possible to raise the acidity of the urine sufficiently to have any definite effect in breaking up the urotropin and setting free sufficient formaldehyde in the bladder to be of any practical use as an antiseptic.

In test-tube experiments this can be easily accomplished by increasing the amount of acid sodium phosphate to the necessary amount, and the fact demonstrated that the drug is then a powerful germicidal agent to all types of organisms. In clinical records, however, we look in vain for any such satisfactory results, although the two drugs have been given extensively with that object. We have most of us met cases of septic or *B. coli* infections of the urinary organs in which, in spite of heavy dosing, the combined drugs have completely failed to bring about any curative result, and it is now generally admitted that clinical results negative any assumption that urotropin is dissociated in the bladder with the formation in any appreciable amount of formaldehyde, and consequently the drug may be written down as therapeutically inert. Any apparent success obtained by its administration in septic conditions of alkaline urine may with sound reason be ascribed to the acid sodium phosphate with which it has been combined.

Jordan demonstrated by means of test-tube experiments that boracic acid in the presence of urine proved inhibitory to the growth of all types of organisms. Unfortunately, however, this laboratory finding does not accord with clinical experience. In actual practice, given by the mouth, boracic acid has proved to have little or no effect on the *B. coli* or on tuberculous infections. It illustrates the necessity of checking all laboratory findings by actual clinical experiment.

My attention was first drawn to the use of boracic acid in bladder conditions in 1892. The case was that of a miner on the Johannesburg goldfields, who was suffering from paralysis of the lower half of the body, including the bladder, the result of an injury to the lumbar region of the spine. Catheterization was necessary, and the urine became very septic and ammoniacal. On the recommendation of Dr. Durr, of Johannesburg, I tried 10-grain doses of boracic acid given by the mouth twice a day. The urine completely cleared in three days, and after that a dose taken occasionally was found sufficient to keep the urine sweet, in spite of the catheterization being carried out by unskilled attendants.

Since this case I have had many opportunities of testing the value of the drug in cystitis and in unhealthy or septic conditions of the bladder associated with calculi, in residual urine in enlargement of the prostate, and as a means of preventing the occurrence of cystitis during the treatment of strictures and in operations on the bladder, such as removal of the prostate or calculi. In all these uses the drug has been found uniformly reliable when given by the mouth; apparently owing to its power of ensuring an acid reaction of the urine. It fails, however, to show any definite therapeutic action in acid urine with *B. coli* present.

The following are some examples of the use of boracic acid:

Case 1.—A man, eighty-three years of age, had for some time found increasing difficulty in passing urine, and the last month had been catheterized daily. In spite of taking acid sodium phosphate and urotropin, his urine remained turbid, alkaline, and unpleasant in odour. His medicine was changed to ten grains boracic acid with five minims of nux vomica three times a day. At the end of three days the urine was acid and clear.

Case 2.—A man, aged seventy-six, had been operated on for enlarged prostate, and was suffering from permanent incontinence of urine, for which he wore a rubber apparatus. His urine was alkaline and septic. He was given five grains of boracic acid with tincture nux vomica three times a day. Three days later his urine was acid and sweet.

Case 3.—A man, aged sixty-four, who was being prepared for a removal of the prostate. He had been on a mixture of acid sodium phosphate and urotropin for some time, but continued to pass a good deal of mucus and pus in the urine. He was changed over to five grains boracic acid and five minims of tincture nux vomica. The urine completely cleared in a week. He made a rapid and uninterrupted recovery from his operation. An occasional dose was given as a prophylactic after operation.

In cases of old men with enlarged prostate who are unsuitable for operation and have to depend on catheterization, and in those cases with a limited amount of obstruction who can manage without catheterization and refuse operation, the administration of boracic acid ensures an acid urine, and the absence of pyogenic organisms. There is neither necessity nor is it wise to keep these cases continuously dosed with the drug, but merely to keep a supply of their medicine handy, and take a dose or so when necessary. I have found it a convenient plan to supply them with a little blue litmus paper, and advise them whenever the urine failed to turn it red, to take a dose or two of their mixture. I believe that if this method of treating the bladder were generally adopted in prostatic cases prior to and after operation, the results would be more satisfactory, and a large number of cases, which under the usual methods of medication are considered unsuitable, could with advantage be submitted to operation.

Boracic acid, when taken by the mouth, not merely renders the urine acid and unsuitable for the Gram-positive bacteria, but also has a healing action on the mucous membrane of the bladder, although no septic infection is present. In the case of a man with a calculus lodged in the prostate, for instance, the administration of the drug not only did away with the irritable condition of the bladder and frequent micturition, but reduced the amount of pus, which microscopically was sterile, from about one-third in the urine glass to a very small fraction within ten days. In simple cystitis the drug cuts short the attack remarkably rapidly. Boracic, or boric, acid (H_2BO_3) was originally suggested by Pasteur, in 1864, as a possibly useful drug in ammoniacal urine, on the grounds of its then recently discovered preservative and anti-fermentation action in putrescible organic fluids such as milk, etc., and not for any bactericidal action. The rôle of the microbe had not then been discovered. It is a weak acid, and, as such, less germicidal than the majority of the mineral acids. In weak solutions it inhibits the growth of some bacteria, but even saturated solutions do not kill pathogenic germs. Certain fungi are, however, killed by very dilute solutions.

When taken by the mouth it is eliminated chiefly in the urine. Although excretion begins within fifteen minutes, and may be quite rapid at first, so that 50 per cent of the ingested quantity will be passed in twelve hours; the balance is excreted more slowly. Thus the drug may be detected in the urine three to five days after the last dose has been taken.

It would appear that the anti-bacterial action of the drug, when given by the mouth, is not due to a true

germicidal action, but rather to its power of rapidly converting alkaline into an acid urine which is no longer suitable for the growth of the Gram-positive pyogenic organisms. Like most active drugs, when given in excessive doses it exhibits poisonous properties, chiefly disturbances of the digestive organs, such as vomiting or diarrhoea and nervous prostration. In doses of five to ten grains, taken two or three times a day, the possibility of any poisonous symptoms appearing may be ignored, especially as it is rarely necessary to continue the administration regularly over a long period. In order, however, to be on the safe side, especially in debilitated subjects, I usually add two to five minims of tincture nux vomica to each dose, and although I have given the drug in a large number of cases, I have never seen any ill effects.

A convenient prescription is the following:

R̄ Aëidi borici	..	60 grains
Tincturae nucis vomicae	..	30 minims
Aquam ad	..	6 fluid ounces
Fiat mist.		

One or two tablespoonfuls to be taken three times a day if necessary. Oral administration is more effective than bladder irrigation in surgical cases.

(2) ACID TYPES OF INFECTED URINE

The colon bacillus is now recognized as far and away the commonest cause of pyelitis, cystitis, and ulceration of the bladder associated usually with acid urine. Cholecystitis and nephritis are not infrequent complications. The colon bacillus is a normal inhabitant of the intestines, and apparently reaches the urinary organs by the urethra or through the lymphatic vessels. Colon bacilli infections are of two types.

(a) *Acute*: in which there are signs of a general toxæmia with constitutional reaction, and usually an intermittent temperature. (b) *Sub-acute or chronic*: in which *B. coli* are found in the urine, without any marked constitutional disturbance, but usually with some symptoms, such as pain in the region of the kidneys, increased urination, and a cloudy, acid urine.

Probably *B. coli* infections of this type are more frequent than is generally suspected, especially among women. The chronic forms may be the sequelæ of acute attacks, in which case the urine is likely to contain a definite amount of albumin.

The diagnosis of colon bacillus infections is in many cases, from merely clinical evidence, a difficult matter. The assistance of the microscope is necessary in order to arrive at a positive conclusion.

(a) The acute forms of colon bacillus infection are sudden in onset, although they may be preceded by those of a sub-acute type, such as pain in the kidneys. Two symptoms are commonly present, namely, an intermittent or remittent temperature, and in many cases nausea or vomiting. The temperature is characteristic, usually intermittent, rising in the afternoon or evening to 100° or 103°F., and returning to normal or sub-normal in the morning. The intermittency or remittency of temperature reminds one of the remittent fever of the allied typhoid infection, the exacerbations taking place at a similar time of the day. Nausea and vomiting may be absent, but in some cases vomiting is very severe and persistent, and is inclined to mislead one as to the true nature of the case. *B. coli* will usually be found to be present in the vomit. The other symptoms vary somewhat according to the organ specially attacked. With cholecystitis, jaundice, pain and tenderness on pressure over the gall-bladder will be present. In pyelitis and nephritis the urine will contain albumin and possibly blood in varying amount, in which case it may be alkaline in reaction. Microscopic and cultivation tests will demonstrate the presence of *B. coli*.

(b) In the diagnosis of sub-acute and chronic forms, the failure of simple lines of treatment, such as the administration of small doses of boracic acid to clear the urine and do away with any symptoms of irritation in connection with the functions of the bladder, should

make one suspect the presence of *B. coli*, and indicates the desirability of a bacteriological examination of the urine.

Treatment.—It is generally admitted that the treatment of colon bacillus infections is unsatisfactory; alkalies, urotropin, vaccines, etc., have all proved largely failures. Personally, I have met failures with all these methods. The administration of boracic acid has also failed to have any effect. One drug, however, namely, monsonia, a South African plant belonging to the geranium family, has given most definite and curative results in the acute type of case, cutting short the vomiting and rise of temperature and rapidly reducing the number of colon bacilli found in the urine. It fails, however, in the chronic or non-feverish type of case. The first case which suggested the value of monsonia in acute colon bacillus infection was one which occurred in 1922, of which the following is a short record.

Case 1.—A woman, aged forty-six, had been suffering for some time from indefinite malaise and pain in the right lumbar region. When I first saw her she was dangerously ill. Severe rigors occurred daily about 4 P.M., with a rise of temperature to 103°F. Headache, nausea, and vomiting; pulse rapid and irregular; pain and tenderness on palpation of the right kidney. The symptoms eased towards mid-night, and the morning temperature was normal, or very slightly above. The urine contained a trace of albumin, the centrifuged deposit showed moderate number of pus and epithelium cells, and numerous coliform bacilli. The symptoms recurred for three days under the methods at first adopted. The gastric disturbance grew worse, and severe vomiting occurred. The vomit showed bacillus coli on culture. With the idea of counteracting the gastric symptoms I ordered the following:

R. Tincturae monsoniae	.. 25 minims
Acidi hydrochloridi dil.	.. 2 minims
Aquam ad	.. ½ ounce

to be taken every eight hours.

The result was that not only did the vomiting cease entirely after the second dose, but the other symptoms showed a marked remission. The third day the temperature remained normal. The centrifuged deposit of urine showed a remarkable decrease in the number of coliform bacilli, so much so that the bacteriologist suggested that those present were possibly contaminations from the external parts. Unfortunately I was not able to follow up the case as I was only temporarily in charge, and handed the patient back to the regular attendant on the fourth day. It had, however, demonstrated the probability of monsonia having a definite action in colon-bacillus infections. The fact that the drug had already proved antagonistic and raised the resistance to *B. typhosus* and the paratyphoid organisms, made it appear that it was not improbable that it would have a similar action on colon bacilli. Since this case a series of interesting results in various types of acute colon-bacillus infections have been obtained, which strongly support this view, and indicate that in monsonia we have a valuable drug for the curative treatment of these cases. The following is a résumé of the evidence:

Case 2. Ulcer of bladder.—A girl, aged twelve years, had been suffering for three years from recurrent attacks of hæmaturia, with painful micturition and an intermittent temperature. *B. coli* were plentiful in the urine, apparently it was a case of ulceration of the bladder. I unsuccessfully treated her at Capetown for one of these attacks prior to my discovering the value of monsonia. She went to England and underwent a three months' course of hospital treatment, including a series of vaccine injections. On returning to Capetown all the symptoms recurred, and I gave her the following mixture:

R. Tincturae monsoniae	.. 15 minims
Acidi borici	.. 5 grains
Aquam ad	.. ½ ounce t.d.s.
ter in die.	

She took this for ten days, and the urine then gave a negative result as regards *B. coli*. She remained free of any recurrence for the next two years, during which she was under observation.

Case 3.—Woman, aged forty, 7th November, 1923. She complained of pain on micturition, with frequent desire to pass urine, for the last three weeks. During the last few days she had suffered from sharp shivering attacks, and rise of temperature with a feeling of faintness in the afternoon. Examination by bladder sound gave a negative result as regards possible stone. Bacteriological examination showed the presence of *B. coli*. Tincture of monsonia, 20 minims, boracic acid, grains five in water, to half an ounce, was prescribed three times a day. By 11th November all symptoms had disappeared, and the patient was normal. She continued taking her medicine for a week, and had remained in sound health for twelve months, when last heard of. A second bacteriological test of the urine was not made.

Case 4. Acute infection very similar in character to Case 1, with heavy deposit of albumin in urine.—Mrs. G., aged sixty, had been complaining for three months of pain in the region of the left kidney. 10th January: was suddenly seized with an attack of vomiting. On arrival at 10 P.M. I found the patient in a collapsed condition with a rapid, irregular pulse, temperature 101.2°F. She had been vomiting bile-stained fluid since 3 P.M., and could not retain even water. I gave her a hypodermic of morphia, gr. ¼, hyoscyne hydrobrom., gr. 1/200, and digitalin, gr. 1/100. She had a quiet night. The next morning I put her on a similar mixture of monsonia as Case 1. The patient steadily improved, but the temperature continued to rise in the afternoon to 99.4, and on the fourth day boracic acid, 5 grains, was substituted in the monsonia mixture for the dilute hydrochloric acid. Two days later the temperature remained normal, and continued so subsequently. The urine at first contained about one-third albumin, this rapidly decreased in quantity, and at the end of two weeks was reduced to a trace merely. After the first ten days the monsonia mixture was changed to one of 5 grains of citrate of iron and ammonia, with 5 minims of tinct. nux vomica. The patient quickly regained strength, and was able to move about at the end of three weeks. I was unable at first to obtain a bacteriological examination; the symptoms, however, left little doubt that *B. coli* were the cause of the trouble.

Case 5. Acute nephritis due to *B. coli* infection.—Girl, aged eight years. 20th May: this patient came under my charge fourteen days after an acute attack of fever, vomiting and hæmaturia. The temperature had been of an intermittent type at first; the last two days before I saw her it had remained normal or sub-normal. The urine, which was heavily charged with altered blood, showed many pus cells, and coliform bacilli in large numbers. She had been on an alkaline line of treatment and milk, which was often vomited. I changed her over to a similar mixture of monsonia and boracic acid, as case 2, and allowed a mixed liquid diet, which was retained. After three days' treatment the urine was again submitted to bacteriological examination. The report was that stained preparations of the centrifugized deposit showed scattered leucocytes and one or two Gram-negative bacilli only. The urine steadily improved in colour, and all symptoms of gastric disturbance disappeared. The urine was again examined on 1st June. It then only contained a trace of albumin; a few coliform bacilli were still present. In taking the urine, precautions were used as far as possible to avoid contamination from the external parts, but could not be guaranteed. In private practice patients object to the passage of catheters for merely scientific purposes.

Case 6. Colon bacillus infection of the gall-bladder.—The patient was a middle-aged woman who had been in bed suffering for five weeks from jaundice, occasional vomiting, pain and tenderness in the region of the

gall-bladder with persistent intermittent type of temperature. Her medical attendant, of whose practice I was temporarily in charge, had diagnosed it as cholecystitis with *B. coli* infection, and had been giving urotropin and alkalies without any effect. After trying 15-grain doses of sulphate of soda three times a day, I changed her over to tincture of monsonia, 25 minims, and dilute HCl, 5 minims, aq. ad 1 oz. t.d.s. The rise of temperature ceased after two days, and the patient was convalescent at the end of a week.

In these six consecutive cases of *acute colon bacillus* infection, five in which the kidneys or urinary bladder were apparently the primary seat of infection, and one in which the gall-bladder was affected, the effect of the administration of monsonia with either dilute hydrochloric acid or boracic acid was very definite and rapid.

(1) Vomiting and nausea ceased after one or two doses, including a case in which *B. coli* was demonstrated in the vomit.

(2) Any intermittent temperature present disappeared by the third day of treatment, except in Case 4, where it did not entirely cease until boracic acid was substituted for dilute hydrochloric acid in the mixture, probably owing to some secondary infection in the bladder, possibly one of the moulds.

(3) The actual disappearance, or very marked decrease, of *B. coli* in the urine was evident after three or more days' treatment in the cases in which it was tested.

(4) The amount of albumin present rapidly decreased, and the general condition of the kidneys improved in two cases in which heavy amounts were present prior to administration of the monsonia mixture. The preparation of monsonia which I have used in England is Martindale's tincture of monsonia.

These cases clearly demonstrate that monsonia when taken by the mouth acts as a selective internal antiseptic in acute types of *B. coli* infection in which those microbes have invaded the tissues and set up a certain amount of constitutional disturbance, as in nephritis or cholecystitis. The drug has, however, one limitation, it does not appear to necessarily prevent the propagation of the *B. coli* in the urine, or possibly at the surface of the mucous membrane of the bladder or hilum of the kidney in non-feverish cases.

In Case 5 it will be noted that although the kidney and general symptoms were rapidly relieved, and the number of colon bacilli most remarkably reduced, after three days' treatment, they were still present to a limited amount in the urine after a fortnight's treatment with the drug. The same persistence of the organisms in the urine was found in a case of a male adult, in which *B. coli* were discovered microscopically without giving rise to any definite symptoms. The patient, who was an old neurasthenic war patient, complained merely of the necessity to get up about twice during the night to urinate. The urine was slightly cloudy. The centrifuged deposit showed many Gram-negative coliform bacilli, a few leucocytes. No red cells or casts. Reaction acid. Cultures gave *B. coli*. This patient was treated with tincture monsonia and boric acid without any improvement for a fortnight. He was then given citrate of potash, 40 grains, three times daily, until the urine was distinctly alkaline, and was then again given monsonia and boric acid. There appeared to be a decrease in the number of *B. coli* present, but they failed to entirely disappear from the urine after three weeks' treatment.

The conclusion, which I think is correct, is that monsonia is ionized in the blood and tissues, and acts in them in a manner antagonistic to the colon bacilli in all feverish cases, but does not act in these microbes when they are free in the urine, or possibly infecting only the surface of the mucous membrane of the bladder when there is no constitutional reaction, such as occasional rise of temperature, to assist its action.

The formula used has varied somewhat. In acute cases it seems desirable to give full doses of tincture monsonia as long as the temperature remains remittent

or intermittent, in order to give the drug the best chance of destroying the infection during that stage, when experience proves it is best able to exert its action. Thirty to sixty minims taken every six hours with 5 minims of dilute hydrochloric acid, or 5 grains of boracic acid and water to half an ounce, is a satisfactory method.

The treatment of the chronic, non-feverish types of *B. coli* infection of the bladder and urine which many observers consider most satisfactory, is the administration of citrate of potash in 30- to 60-grain doses three times a day until the reaction of the urine is alkaline, and after that occasional doses sufficient to keep it on the alkaline side for a lengthened period.

B. typhosus infection of the urine does not appear difficult to get rid of. One case of a private soldier during the war was sent into my wards at Roberts Heights as a typhoid carrier; *B. typhosus* being present in the urine. He was treated with 5 grains boracic acid and 3 minims of tincture nux vomica, taken three times a day. At the end of a fortnight his urine was found perfectly sterile, both microscopically and culturally.

As to tubercle bacillus, we all know that drugs have so far failed to have any definite effect on that organism.

In conclusion I submit that the guiding principle in the treatment of the various types of cystitis should be the reaction of the urine. Alkaline urines, provided blood is not present, are found in simple cystitis or associated with infection by staphylococci or streptococci. Boracic acid administered orally is specific in these cases, chiefly on account of its power of rapidly converting the urine to an acid type. The treatment of cystitis with acid urine, which is commonly associated with infection by *B. coli* with or without marked constitutional disturbances, and sometimes complicated with pyelitis, nephritis or cholecystitis, is a more difficult problem. In acute forms, with intermittent or remittent temperature, monsonia acts as a curative agent. In chronic or sub-acute non-feverish types the production of an alkaline reaction in the urine by the administration of potassium citrate or one of the allied drugs appears to be the best form of treatment.

Mortality in 985 Cases of Diabetes Mellitus

By JOSEPH HAJEK, M.D.

(Abstracted from *New York State Journal of Medicine*, July, 1933, Vol. XXXIII, p. 802)

THROUGHOUT the United States the death rate from diabetes is increasing. In New York City this disease now causes over 1,900 deaths annually, and this despite the fact that the prevention and treatment of diabetes is well understood. The diabetes death rate in this city is about 50 per cent higher than it was only twenty years ago. Most of the deaths are in persons over fifty years of age, and among these there are twice as many victims among women as among men. Following is the record for the past ten years:

DIABETES, DEATHS AND DEATH RATE PER 100,000

Year	Deaths	Rate
1922 ..	1,448	24.4
1923 ..	1,360	22.4
1924 ..	1,177	19.0
1925 ..	1,313	20.8
1926 ..	1,485	23.0
1927 ..	1,461	22.2
1928 ..	1,663	24.8
1929 ..	1,726	25.3
1930 ..	1,784	25.6
1931 ..	1,921	27.1

Since diabetes most frequently occurs in people past middle life, this increase in mortality cannot be explained and may only partly be accounted for by the larger number of persons attaining to 34 years of age and over.

The diminution in mortality at St. Luke's Hospital is considered in this paper with reference to coma, hypoglycemia, arteriosclerosis, infection, surgery, age and sex.

Coma.—Our decrease of 7 per cent in general mortality is entirely accounted for by the 10 per cent diminution in deaths due to coma. Banting's discovery of insulin has taught us to treat diabetic coma and any diminution of mortality in diabetes at St. Luke's Hospital is due to that cause. In the preinsulin period almost all of our coma cases died, while in the post-insulin era out of 21 individual coma cases treated during the past 8 years only 0.57 per cent died. It would appear, therefore, that while our diabetics seldom now die of coma their life is, nevertheless, taken from them by an intercurrent disease, of which arteriosclerosis and infection stand as the chief offenders. It may be argued from the foregoing statement that since the discovery of insulin the life of the adult diabetic has been prolonged. However, according to our figures the average age at death in the preinsulin period was 55 years and remains the same for the postinsulin era. In the early postinsulin period, coma was for the first time in the history of the disease successfully combated. In the later postinsulin years the prevention of coma is practised with gratifying results. Already we see coma due to diabetes four times less frequently than we did in the pre-Banting period. The time is not far off when the occurrence of diabetic coma will be as infrequent as death due to coma is at present. It is much easier to prevent coma than to cure it. With the development of hospitals and clinics for diabetic patients early diagnosis and treatment are made possible. The widespread knowledge of the disease and its dietary management with or without insulin are factors contributing to the diminution and elimination of coma. The complete co-operation of the general wards of the hospital with the diabetic clinic is essential. Social Service training of the patient completes his educational cycle. Thus patients referred to the hospital from the clinic seldom show anything more than moderate ketosis.

In connection with the early diagnosis of diabetes the problem of differential diagnosis between coma due to hypoglycemia, coma due to ketosis, and coma due to other diseases comes up and should be stressed. The following illustrative case may be mentioned. A patient, who had long suffered from diabetes, was found on the street unconscious. She was brought into a hospital, where it was assumed that she was in diabetic coma. Insulin was administered. It was soon found, however, after examination of the blood that the patient was thrown into severe hypoglycemia (hypoglycemic angina?) and that her original state of unconsciousness was due to coronary thrombosis.

Hypoglycemia: We had no deaths the cause of which could be ascribed to hypoglycemia, but its effect causes much morbidity even if of short duration. I have yet to see a patient taking insulin for any length of time who sooner or later does not have an attack of hypoglycemia or of what he takes to be hypoglycemia. We educate our insulin cases and rightly so to watch for the symptoms indicative of this condition and impress upon them the proper measures to be taken to overcome it. Nevertheless, it must be difficult for the patient accurately to interpret the onset of the symptoms which at their very beginning are puzzling to say the least. If the patient is an adult whose insulin career is comparatively recent, he will immediately take steps to combat the symptoms whether his interpretation is correct or not. If the symptoms clear up, he assumes that his actions were proper. If on the other hand, in spite of precaution, the symptoms persist, his mind is assailed with doubts, and the physician's help is then required. Contrarily, if the patient is a child the first symptoms of hypoglycemia are most frequently overlooked and treatment is begun when severe reaction sets in. So that no matter how painstaking our theoretical education of the insulin patient may be, it is,

nevertheless, his own personal experience with hypoglycemia which helps him most. One or two attacks successfully treated by the patient himself give him confidence and set his mind at rest. It is during this period, according to my experience, in the career of the diabetic that severe reactions are most frequently met with. 'Familiarity breeds contempt.'

Does hypoglycemia or its repeated attacks cause any damage? The effect upon children and young adults remains problematical. In the diabetic past middle life the situation is more complicated. At this time cardiovascular and circulatory diseases are met with, and hypoglycemia may at times add sufficient shock to complicate an already serious condition. I am especially referring to cases falling into the group of coronary sclerosis and cardiac insufficiency. In this group of patients an attack of hypoglycemia may have disastrous effects upon the heart in precipitating what Dr. Joslin refers to as hypoglycemic angina. Strict prevention of this condition is indicated and attempted. The difficulties under which the patient has to labour in such circumstances are obvious. The initial symptoms are often most perplexing and the best thing the patient can do is to treat all such symptoms as hypoglycemia until proven otherwise. Such procedure, however, is followed invariably by hyperglycemia and glycosuria, and possibly ketosis, if the patient's interpretation was incorrect. In children the initial symptoms of hypoglycemia are easily overlooked and when finally discovered so that preventive measures may be taken the little patient may be in convulsions. In connection with this statement the case of little D. S. may be cited. This boy is 10 years old and has had diabetes for the past 8 years. He had several admissions to St. Luke's Hospital and was seen by Dr. Joslin in his New England Deaconess Hospital. He has had at least 8 severe attacks of hypoglycemia with convulsions and coma as well as many milder attacks; this in spite of the fact that his mother is exceptionally intelligent and in a sense a specialist in diabetes. The boy is bright, co-operative, and honest. He is a moderately severe diabetic (taking about 30 units of insulin per day), who within 24 hours may pass through the symptoms of hyperglycemia, ketosis, and hypoglycemia. Because of this he is rather difficult to manage. It is easier to treat hypoglycemia than to prevent it, which should certainly be the other way around, but the prevention of hypoglycemia must not be at the expense of insulin.

Arteriosclerosis and infection.—These two diseases continue to take a heavy toll of our diabetic patients. This field is largely unexplored and prevention remains the best insurance for these patients. Frequent periodic health surveys in addition to the proper management of diabetes is even of greater importance to the diabetic than to the non-diabetic. Much is accomplished in this direction, but nevertheless, cardiorenal disease, arteriosclerosis and infection account for 86 per cent of our diabetic mortality.

The percentages of deaths in the diabetic caused by cardiorenal disease, arteriosclerosis, and infection have almost doubled in the postinsulin period, while deaths due to coma decreased tenfold.

The diminution in general mortality at St. Luke's Hospital in the postinsulin period shows that the decrease of 7.4 per cent in our general mortality is entirely accounted for by the 10 per cent diminution in deaths due to coma.

A moderate increase in mortality is caused by arteriosclerosis, infection and malignancy during the post-insulin period. This increase may be accounted for by the great reduction in deaths due to coma, the more widespread diagnosis of diabetes, and by the increase in the number of people living during middle life.

Surgery.—Three out of every ten diabetics admitted to St. Luke's Hospital have a surgical condition necessitating an operation.

The surgical postinsulin group 1923-1930 comprises 257 cases with a mortality of 16.3 per cent a decrease

of 50 per cent as compared with the pre-Banting period.

Age.—The mortality as to age was greatest between 47-70 years.

Sex.—In 1916 Osler gave the sex ratio of male to female diabetics as 3 : 2. In 1931 Dr. Joslin states 'the proportion of males had decreased to 44 per cent in contrast to 47 per cent in 1921 and 55 per cent a decade before'. At St. Luke's Hospital the proportion of males has increased from 44 per cent in 1920 to 49 per cent during the postinsulin period up to 1931. The mortality sex ratio closely approximates the living sex ratio. The redistribution of sex is significant because it has taken place within the short space of two decades.

SUMMARY

(1) The mortality in 827 cases at St. Luke's Hospital decreased 7 per cent as compared with 50 per cent increase reported by the Board of Health, N.Y.C.

(2) The decrease is entirely accounted for by the diminution in deaths due to coma.

(3) A redistribution of the causes of death is taking place. While deaths due to coma diminished tenfold, those caused by cardiorenal disease, arteriosclerosis and infection have doubled.

(4) Surgical mortality in the diabetic at St. Luke's Hospital decreased 50 per cent.

(5) Neoplasm as a cause of death is on the increase in the diabetic individual.

(6) The average length of life of the adult diabetic has not as yet been prolonged by insulin.

The Rural Tuberculosis Problem in the South

By J. N. BAKER, M.D.

(From the *Journal of the American Medical Association*, Vol. CI, 29th July, 1933, p. 333)

Just fifty years ago, Koch discovered the tubercle bacillus. This 'find' proved epoch-making and comparable to the discovery of gun powder, the printing press, the steam engine, the cotton gin and the pneumatic tire, in that each of these has perceptibly modified man's previous mode of living. Within the brief span of a half century and because of this discovery, the world's outlook on tuberculosis has completely changed.

Tuberculosis as 'captain of the hosts of death' has been dethroned. Be the cause what may—and the contributing factors have been legion—this disease has been deposed from its high pinnacle by 'heart disease' and now sulkily sits as the seventh chief offender in this regard. From 1898 to 1908 the death rate from tuberculosis dropped one fourth; in the next decade, that is, from 1908 to 1918, it dropped one third; from 1918 to 1928 it dropped one half. Since 1918 the rate in the United States has dropped from 150 to 70.7 per hundred thousand and that of the Southern conference area from 140 to 80.4.

The reason for the higher mortality rate in the Southern conference area is, of course, the fact that 80 per cent of the Negroes in the United States are to be found in this area. It is a well known fact—the possible causes of which need not here be argued—that the Negro death rate is from two and one-half to three times that among the white population. Unquestionably, the general living conditions and the economic status of the Negro population is poor and has contributed in no small measure to the propagation of tuberculosis. Dublin states that in the fifteen-year period prior to 1926 the reduction in the tuberculosis mortality rate for Negroes was 44 per cent. This should offer encouragement as to the possibilities of improving the tuberculosis situation among Negroes, when the comparatively small amount of work that has been immediately directed to this population group is realized.

It is estimated that there are 250,000 people in the Southern conference area afflicted with tuberculosis. An analysis by McCain of figures available for cases

in adults admitted to sanatoriums in the Southern area during 1930 and 1931 indicates that, of the 9,785 studied, 11.4 per cent were minimal, 42.2 per cent were moderately advanced and 46.4 per cent far advanced. Do not these figures speak volumes? From these facts must be deduced two simple conclusions, to wit: The problem is big and the necessity for early diagnosis is paramount. The keynote of subsequent further progress in the control of tuberculosis must be 'early diagnosis', and this keynote has been clearly struck in our fifty years of experience. We stand to-day not only at the half century mark but also at a point half way up the steep incline where we may well look back over the years of battle and, profiting by the errors and failures of our predecessors, vigorously press forward to a complete solution of this problem.

The status of tuberculosis as a communicable disease is so well founded as to call for no argument on this point. Particular attention, and properly so, has been given in recent years to the relation of the family unit in the propagation of the disease. All factors that are presented in poverty, such as overcrowding, undernourishment and poor environment, of necessity play an important part in the widespread exposure and tubercularization of the population. It requires the spark, a positive sputum, to set off the conflagration, and the intimate contact of the members of a family unit is most favourable for immediate and intensive spread. While extrafamilial contact may be an important factor, the problem is reduced to the family unit with the appearance of manifest tuberculosis in one of its members.

The widespread exposure over considerable periods and consequent tubercularization of the population has been repeatedly demonstrated. Aronson, in a recent survey of the Southern states, found an average of 55 per cent reactors among Negro and white children in rural areas in which all factors are carefully controlled. The Mantoux test, a potent and standardized old tuberculin being used, has proved quite satisfactory. The application of the test on family groups has given valuable information as to the intensity of exposure and source of exposure for each family member. The value of the tuberculin test has been so well proved that it must be included in any comprehensive programme for the study and control of tuberculosis.

If, therefore, in the South, tuberculosis is a family problem, as I believe largely it is, its proper solution and control must revolve about the family physician as the pivotal point in such control. Until recent years the private practitioner has had a most difficult and unpleasant task in the handling of this disease in its many phases. The discouragingly low economic status of the population groups in which most of his cases have occurred has been a tremendous handicap. The physician has been forced to depend on his own ability to diagnose and treat these cases without the facilities for confirmation or assistance with roentgen examination or expert consultation. State and municipal laboratories have been of considerable aid in sputum analysis; but when the records of these laboratories show an average of 20 per cent positive of specimens submitted, this would seem to indicate that this procedure has not been fully or intelligently applied.

The experience of Southern physicians shows that many cases are seen by them but a short time prior to death. This is particularly true in the case of the Negro. With this experience, coupled with the low economic status of the average patient and feeling that death is the usual and immediate outcome, the physician naturally does not wax enthusiastic over either diagnosis or treatment. Such cases cannot bring prestige even though all may have been done that is humanly possible in a short period of time. In the absence of proper institutional facilities, where surgical procedures might be used in selected cases and where cases are too far advanced for rest to be a possible factor in recovery, a physician may do very little in the way of medical skill, except to relieve final suffering.

Organized effort, therefore, which appreciates and strives to overcome the difficulties experienced by the key man—the family physician—seems to offer much hope for success. Teamwork of the finest sort and a sympathetic understanding should exist between each physician of the organized medical profession and the official county or municipal health department. The extent and complexity of the local problem must be presented to both the medical profession and the lay organizations. A study and summary should be made from existing records and presented in acceptable form to each group. It is only in this manner that a broad programme acceptable to both physicians and lay groups may be prepared and executed which will have the whole-hearted and financial backing of all concerned. The official health organization should sponsor and lead in the education of the people and in the publicity and organization necessary to promote the effort. The methods of control advanced and stressed should be early diagnosis and treatment, isolation of all open cases, social investigation and adjustment of unfavourable environment, and intensive education of the public, especially those closely associated with the disease.

PROGRAMME BASED ON LOCAL RESPONSIBILITY

A reasonable programme which might be adopted for joint effort on the part of the physicians and the health organization should be laid down along the following lines:

(1) A programme of education, participated in by all interested agencies, the leadership to be furnished by the organized medical profession and the recognized official health bodies. Such a programme should embrace newspaper publicity, lectures, radio talks, promotional work with families and contacts, tuberculin testing of family groups, arrangement for distribution of sputum cups, laboratory containers and pamphlets, and the institution of isolation procedures.

(2) The investigation and study of the families in all deaths on record in any given community or area. This would include tuberculin testing of all contacts and examination of selected persons or families.

(3) A complete survey of all families in which there exists a known, manifest case of tuberculosis, with the inauguration of all recommended procedures for prevention of spread.

(4) Classification of all suspects on record through local diagnostic facilities. This rather large group can thus be considerably reduced and permits of more intelligent effort where needed.

(5) The stressing of the needs for local hospital and diagnostic facilities and the provision of funds necessary for their maintenance.

(6) In the absence of proper hospital facilities, as is the case in many of the rural sections of the South, treatment of domiciliary tuberculous cases by the local medical profession, with the recognized agencies giving all possible aid in the matter of nursing and control services. This broad plan of co-operative effort is proving helpful in many sections in Alabama and is worthy of more extended trial.

These views, briefly and imperfectly expressed, spring from the concept of local responsibility on the part of each community, be it a township, county or what not, in regard to its own tuberculosis problem, as much so as the building of its almshouses, its jails, its schools or its roads. Spurred on by the insistent urge of its populace, many states have seen fit to take over, almost *in toto*, all their tuberculosis problems in much the same fashion as they have assumed the insane and eleemosynary burden. This is a financial load which many states, and more particularly in the South, in their present impoverished plight, will certainly experience difficulty in shouldering. When one considers the slow turnover in such institutions and the comparatively small percentage, usually not more than 15 or 20, of the total tuberculosis problem actually solved through this plan of state co-operation, one can but wonder whether this is either the sounder or the more economic

channel of approach. No one, to-day, would question an important degree of responsibility on the part of the state; the question is rather how best this responsibility may be discharged. To assume the entire burden, as many states have already done, is one, but an expensive, way. For a state to form a partnership with its various political subdivisions whereby it participates both financially and in the stimulation of a local programme of self aid certainly has much to commend it. The autonomy of local self government is thereby preserved and the initiative and independence of each political unit correspondingly enhanced. For these reasons, the development of the county or the district sanatorium plan, in which the state participates in both a financial and a supervisory way, seems to offer a method of approach which is sound, economically and basically, and which should form at least a beginning for those states whose finances will not justify a more pretentious programme.

To such a modest approach in hospitalization can be added a statewide programme of consultative and x-ray service such as is now being sponsored at many points. Such a scheme, as outlined, which seeks to attack the problem of control from the periphery rather than from the centre, has been planned for Alabama.

PLAN OF LOCAL CONTROL

The problem of tuberculosis control within the several states presents so many variants and is of such complexity as to defy uniformity of approach or standardization of practice. What might apply to one state in affluent circumstances and with a largely urban population would not at all apply to another with a large rural or agricultural population and with cramped financial resources. Into the latter category most of the Southern states fall. Because, also, of the fact that the county forms the political unit of government in the South to a greater extent than prevails in many Eastern states where the township dominates the political picture; organization for many types of health service has been simplified and expedited. In Alabama, for example, where up to now 80 per cent of the counties have been provided with all-time health service, it is felt that the possibilities are promising of further expanding and superimposing on an already existing county setup a simple and workable plan of local tuberculosis control. Up to the present time, so far as my knowledge goes, no one has succeeded in clearly defining the salient points that should be incorporated into such a plan, nor has there been pointed out the superfluous things that need not be so incorporated. Some two years ago and because of the many shapeless gropings in which we were floundering, Alabama's health department set for itself this rather pretentious task. A tentative plan, embracing the cardinal points enumerated, was submitted to the International Health Board of the Rockefeller Foundation and an appeal made for financial aid in its prosecution. After an exhaustive study of every detail, including the proposed field of operation and the personnel to be employed, the Foundation generously consented to make such a study financially possible. This study has been in progress now for one year.

In essence, its purposes are:

(1) To determine the incidence of all manifestations of tuberculous infection under conditions that exist in a rural community and their potential significance in relation to clinically manifest tuberculosis.

(2) To ascertain the principal channels of spread in a rural community and the factors that modify its transmission.

(3) On the basis of the information thus obtained, to devise practical preventive measures suitable to local conditions.

The general plan of procedure will be as follows:

(1) The family or household is the unit of study and all families in which there now exists, or where at some time a member has suffered with tuberculosis, will be the nucleus for the study of the disease.

(2) The search for new cases will be conducted on a countywide basis, all available means being used.

(3) A complete tuberculin survey will be undertaken to include (a) all school children, both white and coloured; (b) adults and preschool children by precincts or beats; (c) municipal and industrial groups. This should serve to indicate the difference in the incidence of infection in town and rural areas.

(4) In areas selected, on the result of tuberculin tests, an epidemiologic survey of the families within the areas will be made, with follow-up roentgen examination of selected positive reactors.

(5) The clinic is mobile and equipped with portable x-ray apparatus. Seven convenient points within the county, where electric current is accessible, have been selected as clinic centres. Provision is always made in preparation of schedules to render prompt service in all cases referred by physicians. Such physician is provided with cards and stamped envelopes to facilitate the immediate reporting of cases.

(6) A fully equipped laboratory is set up in the central clinic, located in Opelika. The value of frequent sputum examinations is emphasized to physicians and patients. A minimum series of ten negative sputums or two successive positives is the strict policy. In all positive sputum cases, bimonthly specimens must be submitted. Specimen containers are stamped, six being given on the first visit, and are submitted by the patient on a prearranged schedule.

(7) All families in which manifest tuberculosis exists are recorded individually, by family, and the observations for each family kept up to date on a family graph.

(8) General educational measures are carried on both by the clinic and by the county health staff. Each manifest case is under the care of the physician chosen by the patient, and excellent co-operation is being had through the organized local profession.

(9) When a sufficiently large group of manifest, sputum positive, tuberculosis cases have been discovered, over the age of 18 years, the preventive phase of the programme will be initiated. This will consist of a division of these families into a study and control series. The only variant in procedure with the two groups will be the initiation of isolation of cases in the study group, the portable, screened cottage, separate screened porches and separate rooms being used when possible. All patients and contacts will be re-examined and serially roentgenographed at intervals.

(10) The administration problem of rural tuberculosis control will be studied intensively in the entire county where hospital facilities are not available.

Obstetrical Errors

By E. FARQUHAR MURRAY, M.D., F.R.C.S., F.C.O.G.

(Abstracted from the *British Medical Journal*,
1st July, 1933, p. 1)

It is important that the art of obstetrics should be as highly organized as possible. If engaged for a case we must assume full responsibility and not relegate to a nurse or midwife those matters which are essentially medical and obstetrical. Again, if we are usually called in by a certain midwife and find a condition which could have been recognized, and possibly prevented, at an earlier stage, then it is our duty to educate that midwife to the value of closer co-operation. One of the biggest errors made, and still being made, by the profession is that of allowing obstetrics to drift into the hands of midwives, clinics, and whole-time officers. Some of this may be inevitable and even desirable, but doctors are losing the supervisory and consultative interest in this work to the detriment of their practices. The backbone of a successful practice is midwifery, followed by child welfare.

ANTE-NATAL CARE

The supervision, manipulations, and decisions concerned with ante-natal care form one of the most fascinating studies in medical art. The absence of this

care is a big error. The multitude of normal labours which occur without such supervision tend to belittle its value and to make people somewhat sceptical. Sooner or later a most devastating tragedy will shock the most casual in this regard. Such comparatively simple and not infrequent matters as the recognition of an occipito-posterior, a breech in a primipara, or a contracted pelvis which invites obstruction may, when properly dealt with, make all the difference between a triumphant success and maternal and foetal exhaustion, bruising, and even death. Ante-natal care is not merely safeguarding the lives of the mother and her child, but also making certain that they will emerge from their joint experience—the confinement—as undamaged from wear and tear as possible. What we have to aim at is that every baby is presenting head first as a polar lie and with its back anterior, and that the relation of the head to the pelvic cavity shows no unfavourable disproportion.

Occipito-posteriors are best dealt with by applying a pad over the child's back, and it is fixed in position with a tight binder. The bladder and bowels are kept empty, and the patient remains in bed for twenty-four hours. If the procedure fails, repeat it at the next week-end; and if it still fails, then apply it at the onset of labour.

In breech cases the error is often in diagnosis: the buttocks are mistaken for the shoulders. Palpate for the head at the fundus, and dip the fingers into the pelvis behind the pubic bones to feel for a deeply engaged head. Finally, make a vaginal examination. By one or other of these means it should be possible to arrive at a diagnosis. In cases of breech with extended legs, the lower pole of the foetus feels very like the foetal head. If faced with a breech presentation in a primipara ask yourself 'Why is it presenting as a breech?' and exclude the presence of a contracted pelvis. If the pelvis is badly contracted leave alone and arrange for a Cæsarean section, but if normal or doubtful then do a version and test the head to the brim. In carrying out a version always lubricate the abdomen with soap or oil; this makes the version easier. If failure results then try under anaesthesia. If there is still failure, then by means of external measurements and a careful estimation of the pelvic capacity per vaginam decide whether or not there is sufficient room for the breech to come through, always allowing for manipulations for possibly extended arms or legs. Failure of judgment in this respect will end in a very difficult extraction with a stillborn child, or, in gross cases, in retention of the head above the brim. Lubrication of the hands, gloved or otherwise, with ethereal soap makes the corrective manipulations during delivery much easier.

Contracted pelves are usually contracted at the brim or throughout. Some are only contracted at or towards the outlet, and they are the more treacherous, as the head engages well and gives an appearance of normality, while late in labour the moulding and caput may suggest proximity and invite a delivery with forceps. Pelvic measurements, therefore, should always be taken of the outlet as well as of the brim. With the more common types of contracted pelvis the head is high and even overriding the brim. This in a primipara is always suspicious, as the head is usually deeply engaged for some weeks before term. Measure the pelvis and test the head to the brim, if necessary under anaesthesia. With a reasonable degree of care it is possible to divide cases into those that *will*, those that *won't*, and those that *may* come through. The first are normal, the second are for Cæsarean section, and the third group should be as small as possible. Such a thing as a trial labour should not be allowed to occur outside a home or hospital, unless expert assistance is available. There is a place for induction of premature labour, but only in cases with minor degrees of contraction, occasionally in primiparae, and rarely in atypical forms of deformity.

Absence of ante-natal care may allow the toxæmia of pregnancy to produce the kidney of pregnancy and its major crisis, eclampsia. Regularity of the bowels, routine urine testing every fourteen days till the last

weeks, when it is done weekly, and, most important of all, encouraging the patient to report any unusual symptom will modify this danger. Oedema is not, as commonly believed by the laity, due to pressure, but is really a manifestation of renal deficiency. Don't hesitate to starve an albuminuric patient. Fluids are essential, and food may be withheld for a week or more with impunity. Fruit juice and stewed fruit and sugar may be given after a period and before proteins are added to the diet. In actual practice the routine testing of urine specimens would be best dealt with by the nurse if it can be so arranged.

The utmost need for ante-natal care is in the case of primiparae, as their first pregnancy and labour is a trial of their pelvic girdles and their metabolism. Multiparae must be watched carefully also. Their kidneys may be damaged, their lax uteri may allow malpresentations. Four such, with previously normal histories, arrived at a hospital with ruptured uteri. They had malpresentations which had been corrected by version. Three of them died. The malpresentations or the versions should have been dealt with earlier.

LABOUR

The dramatic obstetrics which impressed us as students, the difficult versions, embryotomies, decapitations, and so on, were largely owing to the absence of organized ante-natal care. The contrast between a timely Caesarean section in a case of badly contracted pelvis and a similar case dealt with late in labour *per vias naturales* requires no comment.

A great error during labour is to withhold chloroform. The patient's cries are unnerving the household, the atmosphere is tense, the doctor may be urged to terminate labour. Delivery may be the worst possible treatment in such a case. The patient, a primipara, may be only half-way through the first stage of a perfectly normal labour. Put her and the family to sleep by administering chloroform to the patient. Do not forget to do this when called in by a midwife to a case which you have never seen before. Quieten the household, get the history, and make a careful abdominal examination; then wash up and make a careful internal examination, and arrive at your final decision after sizing up the general condition of the mother and the child. Morphine may be given, and also bromides and chloral; but morphine should not be given if delivery is likely to take place within four hours of the injection.

Failed forceps, when analysed, are divisible into those due to errors of omission and those due to errors of commission. The former are neglect of ante-natal care, and the latter are forceful attempts to anticipate natural processes or incorrect attempts to remedy the neglect of ante-natal care. Cases admitted to hospital with the os uteri one-third or one-half dilated are merely given time to complete the natural process. The injection of pituitary extract is open to criticism. Having known of it being given to primiparae, and even primiparae with badly contracted pelves, I believe that the following is fairly sound advice: never give pituitary extract until you are fully conversant with obstetrics, and never to a primipara. Reserve its use for multiparae with a fully dilated os, and a head well engaged or low down, when it is merely a question of pushing or gently pulling the head over the perineum. Always dilute the extract and inject it gradually under anaesthesia. Another common cause of failed forceps is failure to recognize that the baby's head in an occipito-posterior case is not yet in the antero-posterior of the outlet. It is not always easy to detect, especially if there is much of a caput. It is still more difficult if the patient is lying in the left lateral position. Great help is obtained by delivering these patients in the cross-bed position, using either Clover's crutch or the obstetric straps to obtain the lithotomy position. The exact relation of the head to the outlet is then easily detected by inserting the left hand in the vagina in order to palpate it thoroughly, or even to feel for the ears. Once the

condition is recognized, rotate into the correct position and apply forceps, but if impossible to correct manually then correct with the forceps and reapply them, after correction, before extracting the head. Another error is to attempt extension of the head with the forceps before the occipital protuberance on the child's head has descended below the symphysis pubis: feel for it. In the third group of failed forceps are degrees of pelvic contraction. Gross cases are obvious by abdominal examination alone. Moderate cases require a careful examination under anaesthesia of the pelvic girdle and fetal head. Ask yourself what has already been done and what remains to be done. The only possible alternative at this stage, provided the child is alive, may be a Caesarean section or, occasionally, a version. Do not be misled by the small size of the os in bad cases of contracted pelvis into imagining that the patient is still in the first stage. The os may never dilate any further owing to non-descent of the head.

It is a mistake to allow tears to occur, to fail to repair those that do occur, and to admit that they have occurred. The vexed question of tears is so bound up in the public mind with neglect that it is useful to be frank with ourselves and admit that they do arise in a very large number of primiparae. Much can be prevented, much is inevitable. The really important point is to realize when a tear is likely to be inevitable, and to anticipate it by a timely episiotomy, which should be median in position. The indication for this is a tense ostium vaginae which has produced a secondary caput on the child's head, and where, with each pain, there is blanching of the vestibule. This may, if neglected, lead to two sequels: a bursting tear of the perineum, vagina, and labia, and such laceration of the sphincter urethrae as to result in laxity and incontinence of urine later. Failure to repair tears adds to the risk of puerperal sepsis, and possibly, later, of prolapse developing. As a gynaecologist as well as an obstetrician, and knowing how uniformly well properly repaired lacerations heal, I cannot but believe that, whether the blame rests with the profession or more likely, with the midwives, there is simply no attempt to repair much vaginal trauma. One error might be excused—namely, failure to recognize that an intact perineal surface is associated with concealed lacerations. Always examine for them. Repair cannot, with rare exceptions, be accomplished by means of silkworm-gut sutures; they produce an external appearance of approximation, but they rarely manage to produce actual anatomical apposition. In order to effect this catgut should be used, either buried or superficial. Repair the vaginal tube, repair the rectal tube and sphincter when necessary, bring the levators together between them, and finally repair the skin edges. Tell your nurses not to count the stitches or to admit tears. Tell them to admit bruising; the patient and her husband will thoroughly understand, and their minds be peaceful. This is not duplicity, it is common sense. A 'tear' sounds horrible, a 'bruise' sounds reasonable. When the baby has arrived examine at once for tears. If trivial, repair at once with catgut; but if severe, then wait until the placenta has arrived and do a proper and deliberate repair in the cross-bed position.

Another error is mismanagement of the third stage. The main danger is at night when time hangs heavy and one wants to 'get it over'. We are all human; but unless an anaesthetic has been administered, then it is useful to note the time of delivery and to allow at least fifteen to twenty minutes to elapse before worrying about the placenta. Leave the uterus alone, or at most feel it from time to time. It will not let you down. If an anaesthetic has been given, then the uterus may let you down, so it is best to massage it gently and note when the placenta has left. Should it be necessary to go in for the placenta, then always give an intra-uterine douche afterwards. Failure to do this is asking for sepsis. Never allow a binder to be applied until at least one hour after delivery, and palpate the uterus from time to time.

PUERPERIUM

The first three days are probably the most important. Get the bowels open early. An enema is an adjuvant, not an essential. Opening medicine should be given in twenty-four hours' time or earlier. Always be on the look out for sepsis. Influenza, pneumonia, debility, yellow atrophy of the liver, and the breasts are often provided as an explanation for a sequence of events which are in reality due to septic processes. The headaches, shivers, malaise, and temperatures of a septic process are often attributed to influenza if it is prevalent. Chest conditions of septic origin are often manifest within three days of delivery, and to the inexpert might be believed to be of accidental origin. Rapidity of pulse, with practically no other symptom than increasing weakness, can be due to hyperacute sepsis, but may be attributed to shock or hæmorrhage. Jaundice, with only moderate pyrexia, or even in the absence of pyrexia, can be due to a hyperacute hæmolytic streptococcal infection and not to hepatic derangement. Septic temperatures and engorgement of the breasts are common on the third day. Always be on your guard about sepsis; always suspect it; and always look at the perineum and lochial discharges. Never give a vaginal douche without clear proof of vaginal sepsis. In the vast majority of cases it is merely perineal sepsis: therefore arrange for local swabbing with peroxide, 20 volumes, three times a day, followed by a jug douche of borie or weak lysol; and this is all that is needed. If there is vaginal infection apply similar treatment to the vagina. Very occasionally

the uterus is to blame, but not rarely in the first instance. The difficulty of adequate nursing in outlying areas is obvious. The fact remains that such may be essential.

Three errors remain to be dealt with, although there are many others. Lysol, or any other such substance, is quite useful as an inhibitor of bacterial activity. It does not, except in its pure state, act as a reliable antiseptic. The only reliable antiseptic is a preparation of mercuric, such as the perchloride (1 in 1,000) or the biniodide (1 in 1,000). Swabs, hands, and individuals passing from case to case can never be efficiently disinfected if they depend on lysol. With rare exceptions, never examine a patient when she comes to book you. She is nervous and self-conscious, especially if she is a primipara. Internal examinations are a rarity under modern conditions of ante-natal care. Do not tell a woman that she must never have another baby unless such an edict is based on the soundest medical, surgical, or obstetrical grounds. Such advice—in cases met with—has rarely been justified. The patient fears falling pregnant, and is panicked if she does. If such advice is given, whether justified or not, it is strangely out of place that no further advice follows. Finally, we must realize that the very essence and ethics of our existence are based upon the conservation of life itself. Therefore, safeguard the mothers with ante-natal care. Remember, when you are called in to see a case, the importance of time, sedatives, and careful decisions in labour, and always be on the look out for sepsis during the puerperium.

Reviews

THE COLON, RECTUM AND ANUS.—By Fred. W. Rankin, M.A., M.D., F.A.C.S., J. Arnold Bargen, B.S., M.D., F.A.C.P., and Louis A. Bule, B.A., M.D., F.A.C.S. Philadelphia and London: W. B. Saunders Company, 1932. Pp. 846, with 435 illustrations. Price, 50s.

THIS book is the combined work of an abdominal surgeon, a physician and a specialist in rectal diseases, and reviews the existing knowledge of the diagnosis and surgical treatment of disease of the large bowel and rectum, in the light of the accumulated clinical experience acquired in the special division of the Mayo Clinic devoted to this type of work. Those who have visited Rochester and seen the degree of efficiency attained there by the collaboration of specialists will expect a masterly presentation of the subject and they will not be disappointed. Hardly anything is omitted, but it cannot be said that the resulting volume of 800 odd pages is easy reading. Brevity is aimed at throughout, with the result that the text is crowded with references to authorities, supplemented by long bibliographies at the end of each chapter, so that the work is one for the specialist to consult and not for the student or practitioner to read.

It is difficult to summarize the main features of a work which is already so compressed. Nearly three-fourths of the book deal with the diseases of the colon and with operations, leaving little more than one-fourth for the lower rectum and anus, an allocation of space which hardly accords with the relative frequency with which these conditions are met by surgeons. The opening chapter gives a clear and beautifully illustrated account of the anatomy and physiology of the large intestine, incorporating the studies of Alvarez on the movements of the contents of the colon and the functions of the ileo-cæcal sphincter, an account of recent researches on the gastrocolic reflex and the relations between the tonus of the colon and the pyloric sphincter, most important work which has profoundly influenced current methods of radiological diagnosis. A chapter on anomalies of

development leads to a review of the subject of megacolon, of which no fewer than 76 cases have been met with at the Mayo Clinic in the last three years, 62 of them of the congenital type. Except for the relief of acute obstruction, division of the presacral and inferior mesenteric nerves is the operation of election, having the advantage over lumbar ganglionectomy that it does not interfere with the circulation in the lower limbs. Chapters on volvulus, intussusception and diverticulitis follow the usual lines. The granulomata are exhaustively described and one notes that in the Clinic syphilis is regarded as one of the rarer causes of benign rectal stricture, of the 258 cases seen in 10 years only 55 had some evidence of having had syphilis, but even in these proof that syphilis was the actual cause was unsatisfactory and it seems much more likely, as pointed out by Hayes, that gonorrhœa is the commonest cause. These cases are very common in India; syphilis, amœbiasis, ischio-rectal abscess and trauma can be excluded and by far the most probable cause would seem to be gonorrhœal infection either spreading from the vagina or direct. A noteworthy fact in this connection is that in recorded series of cases 80 per cent of the patients are women.

The next four chapters deal with ulcerative colitis, parasitic diseases, mucous colitis, sprue, pellagra, constipation and other purely medical conditions, amongst which intestinal stasis receives only two pages, with the advice that surgical procedures are not required in more than 5 per cent of cases; that Arbuthnot Lane's work is not even mentioned is eloquent of the change of view on this subject. The chapter on carcinoma of the colon is an admirable account of the subject with discussion of the symptoms of the disease as affecting the various sections of the colon, clearly set out in tabular form. For carcinoma of the rectum the operation recommended is a two-stage abdomino-perineal excision, the perineal method being reserved for cases affecting the anal canal. Many tables of mortality and recurrence rates for various procedures are given, but the types of operation and the views of different

surgeons as to operability vary so widely that results are difficult to compare. Furthermore the Mayo Clinic results are complicated by the fact that many of the cases in accordance with the 5-year survival rate of 33 per cent in 551 cases and an operative mortality of 7.7 per cent in the last 260 cases of the combined operation must be considered good for a radical procedure, but it must not be overlooked that Lockhart Mummery claims a 2 per cent mortality and 47 per cent 5-year survival rate for the perineal operation preceded by colostomy, a safer method in the hands of surgeons who only do these operations occasionally. Mummery's series is of course much smaller and not very recent. Recent results of radium treatment are exhaustively reviewed with pessimistic conclusions, but hopes are expressed for better results in the future.

The remaining chapters do not call for much comment. The dangers involved in x-ray treatment of pruritus ani are stressed and destruction of the peripheral nerves by the injection of 40 per cent alcohol is advised, and is stated to have given 80 per cent of cures. Quinine-urethane is advised for the injection of hemorrhoids and the technique is described in detail. It is surprising to find no mention of the strangulation of prolapsed hemorrhoids, a common and most dangerous complication, for treatment of which directions certainly ought to be given. Another omission is the operation practised by Mummery for prolapse of the rectum by stripping up the bowel from the sacrum, packing the cavity with gauze and allowing it to heal by granulation; the results are excellent and the operation is free from danger. The chapter on methods of examination is good but no description or figures are given of the simple and efficient types of electrically illuminated proctoscopes used in the Mayo Clinic, which differ in many respects from the usual patterns.

The chapter on operative procedures is clearly written and beautifully illustrated, sacral anaesthesia is the method used in operations on the anal region, but the procedure is too difficult and trying for the patient to be suitable in India, the method of low spinal anaesthesia used in St. Mark's Hospital is simple, safe and in the hands of the reviewer has given ideal anaesthesia, far superior to any general anaesthetic. In conclusion one need hardly add that the printing and illustrations are of the highest quality; the book is one which every surgeon should possess, it reviews all recent work with a completeness to be found in no other book on rectal diseases.

ROSE AND CARLESS' MANUAL OF SURGERY FOR STUDENTS AND PRACTITIONERS.—By C. F. G. Wakeley, D.Sc. (Lond.), F.R.C.S. (Eng.), F.R.S. (Edin.), and J. B. Hunter, M.C., M.Chir. (Cantab.), F.R.C.S. (Eng.). Fourteenth Edition. London: Baillière, Tindall and Cox, 1933. Pp. viii plus 1487, with 721 figures and 24 plates (16 coloured). Price, 30s.

We welcome the fourteenth edition of this well known book which still maintains its position as the most popular surgical manual in the British Empire.

The first edition appeared in 1898 and that the fourteenth edition is available only 36 years afterwards is evidence of its popularity as well as the fact that it constantly keeps pace with the advances in surgery. The present edition, again the work of Wakeley and Hunter, is no exception to its forerunners as the recent great advances in chest and renal surgery, to mention only two subjects, have both been brought right up to date. The illustrations have also been carefully edited and we note that three hundred new ones have been added including eight new colour plates. In spite of the great advances in surgery and the necessity of constantly adding fresh matter to a book of this nature judicious whittling of subjects that have become of less importance has enabled the editors to keep it within the remarkably small compass of less than

1,500 pages. Nevertheless it would be difficult to discover any essential of surgery in one of the large systems consisting of many volumes, that is not to be found in this comparatively small book also.

This book can still be classed as the best surgical friend of the medical student and young practitioner that is available in the English language. Apart from the value of its contents the method of presentation by the publishers leaves nothing to be desired and they are to be congratulated on being able to produce such a volume for the very moderate price of thirty shillings, and a further recommendation is that the book may also be obtained in two volumes at the same price.

THE TREATMENT OF DISEASES OF THE SKIN.—

By W. Knowlesley Sibley, M.A., M.D., B.C. (Camb.), M.R.C.P. (Lond.), M.R.C.S. (Eng.). Fourth Edition. London: Edward Arnold and Co., 1933. Pp. viii plus 223, with 24 plates. Price, 10s. 6d.

This is the fourth edition of this book the first of which appeared in 1912 and the third in 1920. Additions have become necessary because in the last twenty years ultra-violet ray treatment has become much used and the methods of application have greatly improved. Many new synthetic drugs have also come into use during this period and it has been necessary to include them.

The book is essentially practical and arranged for ready reference. All the skin diseases are arranged alphabetically irrespective of their aetiology or pathology and at the end of the book there are about 150 numbered prescriptions and these are referred to by their numbers throughout the text; such a method greatly lessens the bulk of the book.

Under each heading only a bare definition of the condition named is given and this is followed by outlines of the treatment recommended. Unfortunately little attention has been paid to precise phraseology and many sentences are involved and not at all clear; it is annoying to find, in a book obviously compiled for quick reference, many sentences that one has to pause over and consider carefully before one can arrive at the real meaning implied. Directions regarding treatment are also thickly interspersed with such remarks as a certain drug '..... may be tried', '..... is recommended', '..... has been found useful', etc., but the reader is left in most instances without the benefit of the wide experience of the author being quoted. In a book which obviously is made as short as possible it is surprising to find, under the heading of that rare condition keratoderma blenorrhagica, that most of the space is allotted to a list of the drugs used in treating the acute gonorrhoea of which it is a complication. This might well have been omitted, as it is much too sketchy to be of real use. Also the ten lines devoted to yaws would hardly be sufficient to enable an inexperienced practitioner to deal successfully with this disease. These final comments indicate the reviewer's opinion of the book, which is, that it is a useful compilation of a mass of information in readily available form to those practitioners who have sufficient experience to diagnose skin diseases, but it is not likely to be of much value to those inexperienced in dermatology.

P. A. M.

RECENT PROGRESS IN MEDICINE AND SURGERY, 1919—1933.—By various authors. Edited by Sir John Collic. London: H. K. Lewis and Co., Ltd., 1933. Pp. xii plus 368, with 33 illustrations. Price, 16s.

SEVERAL books have been lately published dealing with recent advances in the various branches of the profession, but no previous attempt has been made to bring together a record of post-war progress in medicine and surgery within the compass of a single volume. Sir John Collic has undertaken the task of editing such

a book and has succeeded in producing a most creditable volume. The subjects are divided into twenty-one chapters, each written by an authority on his subject, commencing with a chapter on endocrinology by the Regius Professor of Physic at Cambridge and closing with a chapter on plastic surgery by Sir Harold Gillies. The articles are uniformly excellent and the editor has succeeded in securing balance in style, length and presentation, a task often difficult when dealing with multiple authorship.

The book is recommended to the general practitioner who wishes to bring his knowledge up to date and to the specialist who desires a summary of recent progress in subjects other than his own. Both will find the material he wants in a single volume of reasonable size and price. But, as is pointed out in a foreword by Lord Horder, it is not a book for the idle hour. It abounds with facts and the field covered is enormous. It should be studied when the brain is fresh; the trouble will be well repaid.

J. C. D.

INTRACRANIAL TUMOURS.—By Percival Bailey. London: Baillière, Tindall and Cox, 1933. Pp. xxiv plus 476. Figures 155. Price, 35s.

INTRACRANIAL TUMOURS have always been a most baffling problem to the clinicians and neurologists. The reason is not far to seek. The tumours are enclosed in a rigid bony case out of reach of the palpating finger, and, in many cases, also out of reach of all modern aids to diagnosis, like the röntgenograms and ventriculograms. Localization is almost impossible because the tumours have a tendency to give rise to symptoms from distant parts of the brain by pressure and circulatory derangements. In spite of these difficulties, it is interesting to see the advances made in this realm through the efforts primarily of the American surgeons.

The book is written by the Professor of Surgery of the University of Chicago and constitutes the demonstrations and clinics given by the author to his students. It is an admirable exposition of the difficult subject and should find a hearty welcome. Most of the illustrations are original and very instructive. Though the subject has been presented from the pathological standpoint, physiological considerations, which form the basis of the study of the nervous disorders and the keynote to the localization of functions of the brain, have not been neglected. Indeed the chief merit of the book is its brilliant exposition of the various symptom-complexes in connection with the cerebral tumours through the help of the principles of physiology. The treatment has been dealt with from the operative point of view and is very thorough both as regards the pre-operative and post-operative details. The subject of anaesthesia in intracranial surgery has also been touched upon.

The get-up is excellent though the author's anathema against glazed paper is not shared by the reviewer. The book is far too advanced to be considered suitable for the ordinary medical student, for whom it is meant by the author. The post-graduate student, however, would find in it a veritable mine of information.

R. N. C.

SOME THOUGHTS ON ASTHMA.—By A. J. D. Cameron, M.B., Ch.B. Bristol: John Wright and Sons, Ltd., 1933. Pp. 174, with 4 plates and 8 illustrations in the text. Price, 7s. 6d.

THOUGH much water has flowed under the bridge since the asthma syndrome was first recognized, the problem has remained as elusive as before. Medical research has probed into the problem from various aspects, but there has been a tendency on the part of enthusiastic workers in some of these fields to neglect due consideration of the other aspects. For some, asthma is merely a psychological problem; for others, allergy and hypersensitiveness to foreign proteins plays the most important part; there is another school

that would ascribe the condition to calcium deficiency and endocrine imbalance; and the toxic element is the primary thing with still another group of workers, who would consider all the nervous manifestations of the disease, as merely due to failure of the nervous system to co-operate successfully in getting rid of the toxin. The author of the book under review is an exponent of the toxic hypothesis, and he has supported his assertion by clinical and biochemical investigation in his clinic for a number of years. 'To his mind, the toxic theory is the only one which is built on a solid foundation, a foundation which will withstand criticism on any side'.

While refraining from making any comments on the rôle of toxicosis in the causation of asthma, it is very difficult in the present state of our knowledge of the problem to subscribe to the views of the author *in toto*. There are certainly other factors which can produce a paroxysm in the absence of an exciting toxin. The treatment recommended is certainly worthy of trial, considering the satisfactory results obtain by the author.

R. N. C.

ESSENTIALS OF MEDICAL ELECTRICITY.—By E. P. Cumberbatch, B.M. (Oxon.), D.M.R.E. (Camb.), M.R.C.P. Seventh Edition. London: Henry Kimpton, 1933. Pp. xiv plus 508, with 15 plates and 132 illustrations. Price, 10s. 6d.

THE number of editions through which this well-known book has been is sufficient proof of its popularity. It has always been noted for simplicity of language and clarity of expression. In this respect the present edition is no exception.

The present volume has been considerably enlarged. The subjects of high frequency and diathermy have been revised and treated in a more complete manner, and now extend to several chapters instead of one. The author, moreover, proposes to include these methods of treatment under the heading electrothermic methods of medicine and surgery, a sufficiently comprehensive term. The expression 'high frequency' is used as a generic term for the currents employed in the various methods described.

In the chapter on medical diathermy, a brief account of the so-called therapeutic fever and the means of producing it is included.

A new series of plates showing not only the situation of the motor point, but also the muscles which they represent, has been provided. In addition to these there are sixteen new illustrations.

The present volume, indeed, can be looked on as a detailed exposition of the subject and is sufficiently complete to take its place alongside the classical works on the subject, such as that of the late Lewis Jones and others.

WHEAT-, EGG- OR MILK-FREE DIETS WITH RECIPES AND FOOD LISTS.—By R. M. Balyeat, M.A., M.D., F.A.C.P. Assisted by E. M. Rusten, M.B., M.D., and R. Bowen, B.A., M.D. Philadelphia and London: J. B. Lippincott Company, 1933. Pp. xi plus 149. Illustrated. Obtainable from Messrs. Butterworth and Co. (India), Ltd., Calcutta. (Publishers). Price, Rs. 7-14.

THE question of human sensitiveness to certain foods as the causative factor in certain allergic diseases has been the subject of controversy for a long time. As the result of recent studies, several definite conclusions have been arrived at. One of the most important amongst them is that food sensitization is the sole cause in some cases of asthma, and a contributing factor in many, and that it is the primary causative factor in a large percentage of cases of migraine and urticaria.

In allergic diseases, as soon as the sensitization of a patient to a specific food-stuff is recognized, that particular food is usually withheld, provided it is one of the uncommon kinds. The real difficulty, however, arises when such food-stuff is a staple constituent of

diet, such as wheat, egg, and milk—which, it is recognized, are extremely difficult to eliminate from the daily dietary.

In treating a large number of such sensitive patients, the authors have realized the importance of wheat, eggs and milk as common food-offenders in allergic diseases and their main idea in writing the present volume is to help physicians and dietitians in the proper selection of food for their patients (who are sensitive to such food-stuffs) by suggesting a variety of recipes, which are wheat-free, egg-free, and milk-free. They will also, at the same time, be of great help to the patients in selecting the proper kind of dietary for themselves.

The book is divided into six parts. The first part deals with the rôle played by food in allergic diseases. Part II deals with the methods of testing adopted for food sensitization while the next part deals with the different types of patient. Part IV which constitutes about two-thirds of the book gives an exhaustive list of recipes for wheat-, egg- or milk-sensitive patients. The next two parts of the book deal with subjects of general interest, such as food requirements of the body, food-values, and height-and-weight tables.

The book is an interesting study and we feel sure that it will be of use to those for whom it is intended.

J. P. B.

FRONTIERS OF MEDICINE.—By M. Fishbein, M.D. Baltimore: The Williams and Wilkins Company, 1933. Pp. x plus 207. Price, 5s. (Agents are: Messrs. Baillière, Tindall and Cox, London.)

THIS book is one volume of a series entitled 'A century of progress'. From the list at the end of the book it is gathered that this series consists of a collection of small volumes on various technical subjects, each being written by an American authority on the subject concerned. From the style of the volume under review, which is the only one of the series that has come into our hands, it seems that these books are essentially written for the general public, with the object of giving a brief outline in simple language of scientific progress along various paths.

Frontiers of Medicine, in our opinion, achieves this object for it gives a good general bird's-eye view of this vast subject. To the critical medical reader the book will probably not appeal for it only gives the barest outlines of the numerous branches of medicine and surgery, and the critic will note certain inaccuracies. One also feels that some steps in our progress have received more than their due amount of attention in a brief general summary of this nature, and that other important discoveries have been glossed over or altogether omitted. The book will also be of much greater interest to Americans than to readers in other parts of the world.

Nevertheless it may be recommended as a book that can be read with profit by the layman as one that will give him a broad general idea of the enormous amount of endeavour that has been expended on his behalf by the medical and its allied sciences in improving his health, prospects of long life and material comfort.

THE EXAMINATION OF WATER AND WATER SUPPLIES.—By J. C. Thresh, F. J. Beale and E. V. Suckling. Fourth Edition. London: J. & A. Churchill, 1933. Pp. xvii plus 824, with 61 illustrations. Price, 42s.

THIS book has been a work not only of standard reference to sanitarians for many years, but the guide, philosopher and friend of many medical officers of health who were distant from laboratories and advice. We doubt whether any public health laboratory could do without it, and whenever any question connected with water supplies arises it is the first book that receives reference. We note with regret that the senior author has died since the last edition appeared. Dr. Thresh

was the originator of the book, and the earlier editions (and indeed the present one) contain much of his personal experience in the examination of waters and in experimental work. If we remember rightly it was his investigations mainly, that disentangled many of the puzzles of plumbo-solvency (though there are still some remaining), and pointed to the importance of the presence of small quantities of soluble silicate in natural waters as a preventive of plumbo-solvency, and to the suggestion for its addition to waters otherwise possessing this dangerous quality.

There is little need to enlarge on the qualities of the present edition. The present authors have maintained the high standard and aims of previous editions and produced a book covering very nearly every aspect of water and water supplies (except the purely hydraulic ones) and one to which the sanitarian, whether medical officer of health or sanitary engineer, may turn with the assurance that his needs will be met, and latest information and references will come readily to his hand.

As the authors state, population and the need for water supplies grow apace. In the past, large towns in England have avoided obvious polluted sources such as large rivers and have constructed large artificial lakes (e.g., Lake Vyrnwy in Wales). But more and more, such towns will be forced to make use of streams and rivers for their water supplies (London is a case in point). Hence modes and means of purifying such polluted sources become more and more important, and the more polluted the source, the higher the standard of purification demanded, and the greater the necessity and demand for more exact and precise means of purification. Thus chlorination, chloramine compounds, ozone and activated carbon are being extensively used now throughout the world for purification of municipal water supplies, and these subjects are fully noted on and the most recent ideas and work described. The aspect is closely bound up with river pollution, and, in the past, legislation in England has not been very strict on river pollution. In the future, however, greater stringency may be necessary. On the vexed question of bacteriological standards for potability, we are perhaps not very much farther forward than we were at the date of the last edition. Of methods of examination there has been a very great increase, and if we were to use every method of examination described, e.g., species differentiation, glucose + and lactose—; utilization of citrate; methyl red, methylene blue and eosin, the Voges-Proskauer reaction; special selective media for the aerogenes group, etc., we are still left with an uncertainty as to what they all mean practically, and how to incorporate such results into some intelligible standard, if this is possible. The lactose-bile-salt method has proved satisfactory to workers in England, but in America it has not found such constant favour, owing to a large proportion of false reactions brought about by Gram-positive and spore-forming bacteria. Various explanations are given for these discrepancies such as the greater pollution of the raw waters in America, the less degree of purification effected there by filtration and the fact that chlorination does not destroy spore-forming bacteria. The result has been a multiplication of methods and media in America aiming at a differentiation of faecal (human) and non-faecal organisms.

In America, the American Public Health Association has produced certain standard methods for the examination of water and sewage which have been accorded a certain amount of acceptance and which we believe are followed by many official health agencies in the U. S. A., especially the Federal, though they have received some criticisms on both sanitary and mathematical grounds. The coli-group test is the basis of the bacteriological standard. The authors of the book under review bewail the fact that no authoritative health agency in England has attempted to bring such uniformity either in methods or interpretation. English

sanitary legislation however rather abhors a standard (e.g., the Food and Drugs Adulteration Acts which contain few standards), and this attitude must naturally be reflected in the British sanitary mind. If any standard for water does exist in England, it would be that there should be no lactose fermenters in 50 c.c.m. This may be considered a high standard, but it is in line with other English standards in factors of safety, for instance in motor car construction and in building principles. If there is any standard for potability of Indian waters, we take it to be 'negative in 10 c.c.m. for lactose fermenters'. Considering the grosser pollution and even making allowance for natural purification we think the English standard to be nearer the desirable mark for India. A similar opinion we notice is gaining ground in Malayan water supplies.

We are sure that every public health worker in India will replace his old copy by this new edition.

AUTOMATIC RURAL RECONSTRUCTION. A SUGGESTION.—By J. C. Ghosh, B.Sc. (Manchester), F.C.S. Published by the author himself. P. 154, Lake Road, Calcutta. 1933. Pp. 116. Price, As. 12.

EVERYONE recognizes the disabilities of village life in India; ignorance, poverty, disease, and debt produce conditions which to the outsider would seem to make life sometimes intolerable. Still, happiness is indefinable in general terms, and perhaps there are to-day more unhappy people outside Indian villages than in them. Nevertheless, there is general agreement that the

amenities and opportunities of civilization should be made available to the villagers of India, who constitute such a large proportion of the population. The problem has received consideration from many sides and many quarters. Missionaries, sanitarians, agriculturists, economists and politicians have made plans and many have practised them with a certain amount of success. The criticism of such efforts has been that movements whose force is directed from without, which are not grafted on to the permanent agencies dealing with village life, and which depend on the virility and energy of particular individuals are bound to fail. The demand for improvement and progress must come from within the villages themselves and be part of the innate national character.

The present booklet by Mr. Ghosh is permeated with goodwill and enthusiasm. He considers that education and upbringing in social service and friendly helpfulness is not fostered sufficiently; that this, and a preparation for a scientific and industrial career, will achieve wonders even in 10 years. The argument is rather loosely put together and suffers from being presented mainly in the form of extracts from articles on special subjects. The greater part of the booklet for instance deals with the Drugs Enquiry Committee and its recommendations, only a small part of which can be relevant to the main theme. If lacking in coherency, the booklet is interesting and has a sympathetic earnestness which must appeal to those who, like Mr. Ghosh, feel that Indian village life deserves the utmost consideration and study, and that its problems lie deeply ingrained in the life and character of the nation.

Annual Reports

ABSTRACTED FROM THE RESOLUTION REVIEWING THE REPORTS ON THE WORKING OF MUNICIPALITIES IN BENGAL DURING 1931-32. GOVERNMENT OF BENGAL. (LOCAL SELF-GOVERNMENT DEPARTMENT)

Public health.—The municipal authorities almost without exception showed energy in dealing with outbreaks of cholera and smallpox. In four municipalities only were there outbreaks sufficiently serious to be described as epidemics and when sporadic cases occurred, as they did in most places, adequate measures were promptly taken, though a few municipalities wasted money on precautions, such as the burning of sulphur and coal-tar in the affected areas, which were not likely to be of practical value. It is satisfactory to note that vaccination and revaccination were carried out as a rule systematically, and that the prejudice against revaccination showed signs of diminishing. For example in Tangail and in Dacca there were for the second year in succession far more secondary than primary vaccinations and in several other places revaccinations were numerous. In Dacca and in Pirojpur, where also revaccination was popular, there was not a single case of smallpox. Against cholera the chief safeguard must always be a really adequate water supply, which is still lacking in the majority of municipalities; but chlorination and disinfection together with anti-cholera inoculation, which appears to be accepted readily, were successful in protecting the towns against the cholera epidemics reported from several districts. It is worth mentioning that at Faridpur cholera attacked only persons who did not use the water from the town water supply.

Municipalities were much less successful in dealing with malaria, which demands, for its control, not intermittent displays of energy but persistence in a definite and well-thought-out programme, giving no immediate results. From all divisions there are reports of activity in filling up tanks and cutting down jungle. But such

activities cannot possibly have any effect on malaria unless carried out systematically and over large areas, and the finances of the municipalities forbid their undertaking them on a sufficiently large scale. It is essential therefore that municipal authorities should compel property owners to collaborate by keeping their premises in a proper state. Increased powers have been given in the new Municipal Act which it is hoped will lead to an improvement in this respect, but they will not do so unless the municipal authorities use them with greater firmness than as a rule they do their present powers. Just as frequently they hesitate to incur unpopularity by insisting on the prompt payment of taxes, so too they are reported in many instances to have taken no steps to enforce the orders issued by them on owners of private lands to carry out sanitary improvements. It is possible that in this direction they may find their task made easier by the activities of anti-malarial societies which are reported to have done good work in several towns; supported by a popular movement against insanitary conditions in a definite area, the municipal authorities are in a better position to take coercive measures than when they act on the reports of their public health staff only. At Birnagar the Palli Mandali continued its anti-malarial campaign and in addition undertook measures against mosquito breeding in the Choka Bheel on the outskirts of the town; and in a few other towns anti-malarial campaigns were carried on with the assistance of the public health department. It may be noticed that reluctance to cut down expenditure on sanitation led in many places to neglect of other important activities and in particular of the upkeep of roads.

Activities against the sale of adulterated food-stuffs were very uneven. For its size, the small town of Gaibandha did most, instituting no fewer than 40 prosecutions. The total number instituted by the municipalities of the whole Presidency Division was only 20 more. Out of this total 31 were instituted in Berhampur, resulting in fines of Rs. 540. At Dacca

there were 94 prosecutions but the fines amounted only to Rs. 196. The municipalities of Dacca Division on the whole showed the most energy against the sale of adulterated food-stuffs, and among the most active of them was Nalchiti, one of the smallest. Rajshahi Division held the second place, but generally speaking little was done in the other divisions. One of the commissioners points out that in prosecutions initiated by district boards the failure of municipalities to check the sale of adulterated food-stuffs by wholesalers has been successfully pleaded as a defence by small shop-keepers in villages, who have to buy from them. This is a matter to which municipalities in general might devote more attention. The other activities of the municipalities as regards public health work during the year under review call for no special comment.

ABSTRACTED FROM THE ANNUAL CLINICAL REPORT OF THE GOVERNMENT HOSPITAL FOR WOMEN AND CHILDREN, MADRAS, FOR THE YEAR 1932

A TRIAL of nebulinal and chloral hydrate to relieve the pains of labour has been made in the case of 50 European and Anglo-Indian women. The treatment has been tried on European and Anglo-Indians in the belief that one might expect more accurate information on the results of the treatment from this class of women than from the average Indian hospital patient. The method followed was that of O'Sullivan and Craner as far as possible. The results may be summarized as follows:—

All patients sleep for varying periods after taking the drugs. Some awake with the pains, whilst others are roused, and a few do not even move with the pains. Some patients can be roused easily and could be made to talk and answer simple questions rationally, though slowly. Other patients are roused with difficulty and then drop back to sleep. A third group cannot be roused at all. Amnesia was present in about 80 per cent of the cases that had the complete course of treatment. Even in patients who received only a partial course, the pains of labour were greatly diminished, and often very little was remembered. Restlessness was noted sometimes, but was never present to a marked extent. Uterine contractions are not appreciably diminished but sometimes there is delay with the head at the outlet, owing to the absence of voluntary expulsive efforts. Forceps were applied in six cases for this reason. No other bad effect on labour has been noted, and there is no tendency to post-partum hæmorrhage.

The treatment produces, as far as we can judge, no bad effects on the cardiovascular, respiratory, urinary or alimentary systems. There are absolutely no bad effects on the child. When the treatment is combined with a little chloroform administered as the head is being born, a practically painless labour results.

Spinal anaesthesia with novocaine has been the routine anaesthetic employed by the superintendent for all except very short operations. When one has experienced the tremendous advantages of spinal anaesthesia in pelvic surgery, one would be very sorry to have to return to general anaesthesia, particularly where expert anaesthetists are not available.

ABSTRACT OF THE EIGHTEENTH ANNUAL REPORT OF ST. DUNSTAN'S

OVER 120 of the war-blinded men of St. Dunstan's are now chartered masseurs with successful practices in different parts of the Empire. Doctors have spoken with enthusiasm of the peculiar skill of blinded men in this highly specialized branch of work. Many other St. Dunstan's men are employed as telephonists. A blinded telephonist can operate a fifty-line switch-board and take down messages in Braille shorthand at

100 words a minute without turning a hair. War-blinded officers and men are also to be found undertaking directive and administrative work, and there are persons, lawyers and public men amongst them. The majority, however, are employed with their hands at such jobs as joinery, boot-repairing and basket-making.

This report makes it quite clear that although most of the two thousand war-blinded British soldiers and sailors trained at St. Dunstan's are now comfortably settled in homes of their own and living lives that approximate very closely to those of normal citizens, the work of St. Dunstan's is by no means finished—nor ever will be until the last of them is no longer living. The same organization that set them on their feet now helps by every possible means to keep them there, pledged to look after their welfare in sickness and health for the rest of their lives. Their courage and cheerfulness are almost proverbial; but it must make all the difference to them to know that St. Dunstan's is still behind them; and that behind St. Dunstan's is, as always, the sympathy and practical support of the British public, who know the debt they owe to these men, and never fail to discharge it.

ANNUAL REPORT (1932) BY THE CURATOR OF THE LABORATORY, WITH REPORT THEREON BY THE COUNCIL, ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

ANTIRABIC TREATMENT

THE superintendent has continued his examination of the statistics of antirabic treatment, collected by the Health Section of the League of Nations from the various institutes of the world in accordance with the resolution of the International Rabies Conference (Paris, 1927). A second review referring mainly to treatment during the year 1929, the results of which were described in last year's report, has been published. A third review dealing with statistics relating to 69,541 individuals, treated mainly during the year 1930, has been completed and has also been published. The conclusions arrived at are virtually the same as those deduced from the earlier figures. No evidence has been found which suggests the existence of a superiority of any one method of treatment over any other, or, more generally, there is no evidence of the existence of a superiority of treatment by live vaccines over treatment by killed vaccines. On the other hand it would appear from the figures examined that liability to post-vaccinal paralysis varies significantly according to the method of treatment employed, the liability after treatment by live vaccines being greater than the liability after treatment by killed vaccines. A number of points have emerged from the examination of the figures for the third period, and of those for the three periods combined (170,904 persons treated). For the further elucidation of these questions, larger statistics are necessary. The statistics relating to a fourth review are now being extracted.

DISEASES OF INDUSTRY

A fresh and promising line of research has this year been commenced with regard to industrial diseases. With the co-operation of Dr. J. C. Bridge, M.R.C.P.E., H. M. Senior Medical Inspector of Factories, and Dr. Thomas Ferguson, F.R.C.P.E., Inspector of Factories in Scotland, relations have been established with the Factory Department of the Home Office. Already various investigations have been initiated, in the carrying out of which the medical authorities of the Home Office are co-operating closely with the several members of the laboratory staff.

(1) In the first place, as mentioned in previous reports, Colonel Harvey is adding to his cabinet-gallery pathological specimens relating to industrial diseases. With this in view, material is being collected

by Dr. Ferguson in Scotland, and, through his colleagues in the Home Department, from England. Already some progress has been made. No such collection of microscopic specimens exists elsewhere.

(2) Colonel Harvey has also been working at the pathology of toluene poisoning, which occurs industrially amongst users of this solvent. He is now engaged in experimental work on animals upon the effects of benzene and toluene poisoning upon the blood and blood-forming organs and the nervous system. Toluene appears to be less toxic than benzene chiefly because it is less volatile.

(3) Work has also been undertaken by Dr. Kernack in the Chemical Department upon indications of nitro-benzene poisoning in samples of urine, in the hope that it might be possible to detect its presence at a stage before symptoms had developed. A method was elaborated capable of detecting one part in 500,000. In a series of specimens from workers exposed to the vapour of nitro-benzene no significant quantity was detected in any instance.

(4) Colonel Liston is also attempting to discover the cause of the skin sepsis which is prevalent amongst workers in jute factories.

Correspondence

ON THE THERAPEUTIC VALUE OF THIOSARMINE IN THE TREATMENT OF SYPHILIS

To the Editor, THE INDIAN MEDICAL GAZETTE

DEAR SIR,—I read with keen interest the article in your February number, by Lieut.-Col. A. Denham White, M.B., B.S., F.R.C.S., I.M.S., and others, on the therapeutic value of thiosarmine, and have looked through your pages since then in the hope of finding comments, from other doctors of the status of the authors of that article, regarding the accuracy of the statements made in that article. The point to which I should like to draw particular attention is the way in which a course of five grammes of thiosarmine is shown to produce slightly better results than a course of one gramme of sulfarsenol.

In the same way the authors compare a course of five grammes of thiosarmine with one of three grammes of novarsenobillon.

They claim that larger doses of sulfarsenol and novarsenobillon are not well tolerated by patients. This is not the experience of many other doctors.

I consider that these statements are misleading.

Finally, I would like to draw the attention of your readers to the fact that thiosarmine is a preparation made by one of the authors of the article in question.

Yours, etc.,

G. V. HANUMANTHA RAO, L.O., L.M.P. (Mad.),
L.C.P.S. (Bom.).

GOVERNMENT HOSPITAL,
GUNTUR,
20th October, 1933.

DANGERS OF EXHAUST FUMES

To the Editor, THE INDIAN MEDICAL GAZETTE

DEAR SIR,—After having read the notes on the dangers of exhaust fumes, in the *British Medical Journal* of 3rd December, 1932, I am tempted to write about a similar incident in this country.

In Petlad in the month of May there was a marriage procession which I attended. In the procession the bride and the bridegroom were sitting in a motor car. All the ladies that followed were just behind the car, and, as is common in processions, it moved slowly, stopping every few yards. The engine of the car was naturally kept running. The result was that after

some time ladies behind began to faint one after the other. Twelve ladies had to be removed to their homes and it was only after some considerable time that they revived.

It is very common nowadays to use motor cars in processions, but the practice should be discouraged. Either cars should be disallowed altogether or they should be kept at the tail end of the processions to avoid such mishaps.

Yours, etc.,

K. V. ACHARYA, M.B., B.S.,
Medical Officer.

CIVIL HOSPITAL,

PETLAD,

17th October, 1933.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL C. A. SPRAWSON, C.I.E., V.H.S., Surgeon-General with the Government of Madras, is appointed to officiate as Director-General, Indian Medical Service, with effect from the 29th October, 1933, during the absence of Major-General Sir John Megaw, K.C.I.E., K.H.P., on leave.

Major-General C. W. F. Melville, K.H.P., to be Deputy Director of Medical Services, Eastern Command, Dated 2nd September, 1933.

Lieutenant-Colonel H. W. Acton, C.I.E., Professor of Pathology and Bacteriology in the School of Tropical Medicine, Calcutta, on leave, is appointed as Professor of Tropical Medicine in that institution, with effect from the 15th July, 1933.

Lieutenant-Colonel M. Das, M.C., is appointed to act as Superintendent of the Midnapore Central Jail, with effect from the 16th October, 1933.

Lieutenant-Colonel B. Gale is appointed to officiate as Civil Surgeon, Simla East, with effect from the date on which he assumes charge of his duties.

Lieutenant-Colonel S. S. Vazifdar is allowed to return to duty, with effect from the forenoon of 5th November, 1933, and is appointed as Professor of Medicine and Clinical Medicine and Therapeutics, Grant Medical College, and Physician and Superintendent, J. J. Hospital and B. J. Hospital for Children. The unexpired portion of the leave granted to Lieutenant-Colonel Vazifdar is cancelled.

Major A. H. Harty is permitted to return to duty on 23rd February, 1934, and is appointed to officiate as Civil Surgeon and Superintendent, B. J. Medical School, Poona, *vice* Lieutenant-Colonel R. H. Candy, I.M.S., proceeding on leave. The unexpired portion of Major Harty's leave is cancelled.

The services of Major M. Fazl-ud-Din, O.B.E., are placed permanently at the disposal of the Government of the Punjab, with effect from the 12th September, 1930, for employment in the Punjab Jail Department.

The services of Major R. S. Aspinall are placed at the disposal of the Chief Commissioner, Delhi, for appointment as Civil Surgeon, New Delhi, with effect from 16th October, 1933.

Captain C. L. Pasricha, a Research Worker under the Endowment Fund of the School of Tropical Medicine, Calcutta, is appointed provisionally as Professor of Pathology and Bacteriology, School of Tropical Medicine, Calcutta, with effect from the 15th July, 1933.

The services of Captain M. Taylor are placed at the disposal of the Government of Bombay, with effect from the 25th September, 1933, for appointment as Officiating Superintendent, Central Mental Hospital, Yeravda.

The probational appointments of the undermentioned officers are confirmed. The order of seniority is as now notified:—

To be Captains

R. W. H. Miller (now Major), 28th January, 1925, with seniority 9th April, 1923.
W. Aitchison, M.C. (now Major), 28th January, 1925, with seniority 20th June, 1921.
Lieutenant J. H. Crawford, 11th May, 1932, with seniority 26th December, 1930.
G. R. M. Apsey, 20th April, 1932, with seniority 22nd May, 1931.

To be Lieutenants

D. M. Fraser (now Captain), 28th January, 1925, with seniority 9th April, 1923.
J. D. Grant, 20th April, 1932, with seniority 20th April, 1931.
W. H. G. Reed, 2nd August, 1932, with seniority 2nd August, 1931.
T. E. Palmer, 2nd August, 1932, with seniority 2nd August, 1931.
W. J. Poole, 2nd August, 1932, with seniority 2nd August, 1931.
C. J. H. Brink, 25th August, 1932.

The undermentioned appointments are made:—

To be Captain (on probation)

N. J. U. Mather, 15th August, 1933, with seniority 16th September, 1931.

To be Lieutenants (on probation)

J. G. Stoneham, 1st August, 1933, with seniority 1st August, 1932.
B. F. B. Russell, 1st August, 1933 (seconded).

LEAVE

Colonel L. Cook, C.I.E., Inspector-General of Civil Hospitals, Bihar and Orissa, is granted leave for 4 months, with effect from the 24th October, 1933.

Lieutenant-Colonel V. N. Whitmore, O.B.E., Civil Surgeon, Simla West, is granted leave, with effect from the 1st November, 1933, to the 28th February, 1934. His services are placed at the disposal of the Government of the Punjab, with effect from the 1st March, 1934.

Lieutenant-Colonel R. H. Caudy, Civil Surgeon, and Superintendent, B. J. Medical School, Poona, is granted leave for 8 months, with effect from 24th February, 1934, or date of relief.

PROMOTIONS

Captains to be Majors

F. E. B. Manning. Dated 3rd October, 1933.

G. J. Smith. Dated 7th October, 1933.

Note.—(i) The promotion of Lieutenant-Colonel H. S. G. Haji, M.C., to the ranks of Major and Lieutenant-Colonel is antedated to 25th July, 1924, and 25th July, 1932, respectively.

(ii) The promotion of Major A. M. Ghosh to the rank of Major is antedated to 19th August, 1927.

Lieutenant to be Captain

Lieutenant (on probation) B. A. Porritt to be Captain (provisional), (on probation), 26th July, 1933.

The undermentioned Lieutenants (on probation) are granted antedates of seniority to 1st August, 1932:—

F. V. Stoneham.

J. M. Matthew.

F. I. Ashton.

I. Feinholz.

RETIREMENTS

Major-General W. C. H. Forster, C.I.E., V.H.S., with effect from the 19th July, 1933.

Lieutenant-Colonel G. E. Malcolmson, with effect from the 30th September, 1933.

Captain J. Acheson, on account of ill-health, with effect from the 1st August, 1933.

Notes

PEDIATRICIANS AND COW AND GATE MILK FOOD

At the close of the International Paediatric Congress held in London and opened by the Duke of York on 19th July, a number of the delegates accepted the invitation of Messrs. Cow and Gate, Ltd., to inspect their processes and methods at their West Country factories.

The party which numbered over 80, and included specialists in infants' diseases from fifteen different countries, was conveyed by express train specially chartered for the occasion to Wincanton in Somerset, the nearest of the zone of the company's factories in the famous pasture lands of the West.

On arrival the delegates were divided into parties and toured the works under experienced guides, aided by interpreters. Great keenness and interest was displayed throughout by the visitors, particularly as the much discussed question of safe milk supplies for children had been the subject of one of the principal papers at the Congress, and had given rise to a lengthy debate. It was generally agreed that Messrs. Cow and Gate had solved the question not only from the hygienic, but also from a nutritive point of view and American doctors present, accustomed to a high standard of milk production in their own country, declared they had never seen such immaculate methods and precision.

The delegates were shown the astounding aggregation of mucus, pus and infective microbial matter extracted at the factories from high grade, strained and apparently 'pure milk' before the actual processing took

place. Recollecting that raw milk of this description would be freely sold to the public, for infant feeding purposes, the exhibition was fittingly described by the guests as 'hair-raising'.

Some of the special foods prepared by the company were also on exhibition, such as Allergilac, for the treatment of allergic conditions in infancy. This food had been particularly referred to by Dr. Bray and other paediatricians at the Congress in the symposium on allergy.

At the end of the inspection the delegates sampled the crisp and creamy product which had been processed throughout to completion for their benefit and an adjournment was made for lunch to the White Horse Inn, a famous old hostelry of hunting renown.

After lunch the delegates drove by motor coach to Somerton factory in the vicinity of Glastonbury and enjoyed the delightful drive through the charming Blackmore Vale with its reminiscences of Thomas Hardy and of William Barnes, the Dorsetshire dialect poet.

SURGEONS GLOVES

We received a few pairs of their 'special process' surgeons gloves from the Leyland and Birmingham Rubber Co. (India), Ltd., with a request to give an opinion on their quality. They were handed to one of the leading surgeons of Calcutta who has informed us that these gloves are equal to any that he has ever used.

The address of the company is 12, Mission Row, Calcutta.

ADEXOLIN LIQUID

This preparation contains vitamins A and D in the proportions natural to high grade cod-liver oil, but at twenty times the concentration. Its potency is specially designed to secure flexibility in dosage—namely, to facilitate the administration of the smallest prophylactic or the largest therapeutic dose; and being practically tasteless and odourless it can be administered without risk of producing nausea. This preparation is valuable not only for all the purposes to which cod-liver oil prophylaxis and therapy have been applied, but like the capsules can be used for massive vitamin therapy as well. It is specially recommended for incorporation in the bottle feeds of infants.

THE TREATMENT OF TUBERCULOSIS WITH SANTUBEN

We have received a report from Dr. Eckstein at the Sanitarium Tatra Matliary in which he describes the use of this form of tuberculin in all forms of tuberculosis, and his summary is as follows:—

In the santuben treatment we have a very useful and absolutely harmless tuberculin specific. It is indicated in all cases where a specific irritance therapy is employed. Its influence on the general state of health, on the temperature and on the quantity of sputum was in most of the cases quite obvious. In no cases could a reaction to the nidus, or a general reaction be observed. The influence on the resorption of the serous discharges was also very evident, and discharges were quickly made to disappear.

DIGOXIN

In recent years it has been recognized that the leaves of *Digitalis lanata* have a much greater cardiotonic action than those of *Digitalis purpurea*, the species commonly used in medicine. Chemical investigations carried out in the experimental laboratories of the Wellcome chemical works resulted in the discovery and isolation of a new crystalline glucoside, which has been named digoxin. After pharmacological examination at the Wellcome physiological research laboratories the glucoside was submitted to the Therapeutic Trials Committee of the Medical Research Council, London, for clinical investigation. The results of this trial have recently been published. They indicate that digoxin is a useful member of the digitalis series, being particularly valuable in the treatment of auricular fibrillation when rapid effects are desired. Digoxin is rapid in its action even when given orally, so that intravenous injection is unnecessary save in exceptional cases. As a pure substance with well-defined chemical and physical properties digoxin provides a digitalis preparation of constant activity requiring no biological standardization. It has now been made available to the medical profession by Messrs. Burroughs Wellcome & Co., in whose laboratories it was discovered. The following products are issued, for oral administration: 'Tabloid' Digoxin 0.25 mgm. (bottles of 25 and 100) and Solution of Digoxin 0.5 mgm. in 1 c.cm. (bottles of 30 c.cm. and 250 c.cm.); for intravenous administration: 'Hypoloid' Digoxin 0.5 mgm. in 1 c.cm. (boxes of 10).

LACTOGEN

A SUBSTITUTE FOR MOTHERS' MILK

LACTOGEN is fresh cow's milk, modified and dried by a process embodying the latest scientific improvements, behind which stands the reputation of the Nestlé Company, as manufacturers of milk products for more than fifty years.

The chief chemical and physical properties of lactogen may be summarized as follows:

(1) When properly dissolved in water its composition very closely resembles the composition of human

(2) Every precaution is taken so as to enforce a strictly uniform composition of the manufactured lactogen.

(3) Extensive clinical tests prove that the digestibility of lactogen is materially in excess of that of best cow's milk.

In cow's milk, the fat exists in comparatively large globules. The modified fresh cow's milk, just before it is dried up into lactogen is forced under considerable pressure through minute openings which break up the fat globules into particles about ten times smaller in diameter; thereby the surface of the fat globules is enormously increased and the digestibility of the fat is increased in proportion.

Furthermore, experience teaches that whereas the curds formed by fresh cow's milk are thick and tough, the curds formed by lactogen are finely divided, exactly as is the case for human milk. These qualities obviously enhance the digestibility of lactogen.

(4) Extensive tests have been carried out in Nestlé's laboratories in regard to the vitamin contents of lactogen and a large number of biological experiments have proved that vitamins A, B and D are contained in this product. As far as vitamin C is concerned, it is directed that orange juice, which contains the anti-scorbutic vitamin in quantity, should be given daily to the baby, in order to guard against any possible deficiency in vitamin C in the milk.

This addition of fruit juice supplies a safety factor and is just as essential when an infant is fed with cow's milk or even at the breast.

(5) Bacteriological examinations are constantly carried out on the contents of the tin as packed for the market, and the results indicate the presence of not more than 500 colonies per gramme on an average. In addition, the pasteurization process has removed the danger of pathogenic organisms.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*,' Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers for the previous year Rs. 2-8 each, and all other back numbers (if available) Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, or creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.
